THE AMERICAN EDITION

OF THE NEW

EDINBURGH ENCYCLOPÆDIA.

MEDICINE.

Sect. XIX. *Variola. Small-Pox.*

WE now come to the second genus of the Pyrexiæ, the Exanthemata, diseases consisting of fever, upon which supervenes, at a certain period, a cutaneous eruption, characterzied by specific symptoms, and continued during a certain length of time; they have also the peculiar property of occurring once only during the life of the individual, and they appear to be always produced by a specific contagion. The diseases to which the above character strictly apply, are Variola, Vaccinia, Varicella, Scarlatina, and Rubeola.

The disease of Variola, or small-pox, which a century ago was scarcely less dreaded than the Plague itself, affords a memorable example of the triumph of the medical art over what appeared to be an inevitable evil attached to human existence. By the introduction of inoculation, the disease was rendered comparatively safe to the individual, and by the substitution of the vaccine for the variolous poison, this benefit has been extended to the community at large. Some time must be allowed for the prejudices of mankind to subside, but we have every reason to hope that ultimately this destructive scourge will be banished from all civilized countries. According to the degree of violence with which Variola exists, it constitutes two varieties, which, although evidently belonging to the same disease, and convertible into each other, differ essentially in their symptoms, and require different modes of treatment; from the peculiar appearances of the eruption, they have obtained the names of distinct and confluent.

The first invasion of small-pox is marked hy symptoms of general fever, which partakes of the inflammatory type, and is characterized by vomiting, and by pain upon pressing the region of the stomach. On the third or fourth day, the eruption begins to appear on the face, and in about two days is completed over the body. It appears in the form of small red points, which afterwards rise into pimples, and at length, by the fifth or sixth day, are converted into vesicles, containing a light yellow fluid. These vesicles are surrounded by an inflamed margin, so as to produce a considerable redness over the whole surface of the body, which is not actually occupied by the vesicles themselves; and all the soft parts, especially the face, is so much swelled, that the eyelids are often completely closed. About the eleventh day, the fluid in the pustules becomes opaque, and of a yellower colour, and being now fully matured, the vesicles burst and shrivel up, and the inflammation gradually subsides, leaving red marks upon the skin, which, when the disease has become violent, are succeeded by pits or depressions, that are never afterwards obliterated. The pustules on the other parts of the body proceed in the same order with those on the face, but go through their successive stages a day or two later, and are generally attended with less inflammation.

In the distinct and less violent form of the disease, the fever abates when the eruption is completed, and seldom returns in any considerable degree; but in the confluent variety, what is called the secondary fever comes on at the period of maturation, which is often equally violent, and is indeed more to be dreaded than the first, or the eruptive fever. All the symptoms are more urgent in this variety, and come on at an earlier period, although at the same distance of time from each other; the pustules are more numerous, so as to run into each other, and form large patches of continuous suppuration, while, at the same time, they are less elevated than in the distinct kind, and have less inflammation round their margin. The fever is also of a different nature, exhibiting more of the typhous type, and the system in general seems to be more oppressed and torpid, and to be less capable of reaction. The prognosis of the disease depends very much upon the nature of the variety to which it inclines; for while, in the distinct Small pox, we may generally hope for a favourable issue, the confluent is, for the most part, altogether beyond the reach of our remedies. What circumstance it is which produces the two varieties we know not: it depends, in a great degree, upon what may be called the prevailing character of the epidemic; in some the distinct, and in others the confluent, being much the most frequent; but we are not able to connect these differences in the nature of the epidemic with any external circumstances, or with any peculiar states of the constitution. We have sufficient evidence that it does not depend upon any specific difference in the nature of the contagious matter; because both the varieties are capable of being produced from the same source of infection.

Small-pox is always produced by its own specific contagion; and when once the individual has gone through the disease, in however slight a degree, he is secured from any future attack. Upon this fact is founded the practice of inoculation; for we learn, that where a portion of the matter is inserted under the cuticle, it will communicate a much milder disease than one that is received in the usual way, which is probably by the lungs. We are, however, totally unable to explain the cause of this difference. The relation which the fever bears to the eruption, or the degree in which one is to be regarded as the cause of the other, is a point that has given rise to much speculation. According to the humoral pathology, the eruption was thought to afford a remarkable example of the critical discharge of an offending matter from the system; and, proceeding upon this principle, the great object of the practitioner was supposed to be, to promote this discharge; a system which led to a practice precisely the reverse of the true one, and which must no doubt have proved highly destructive. In what way the fever operates, or what is the proximate cause of the disease, we know not; but it appears that the eruption is the consequence of the fever, and that, whatever diminishes the fever diminishes the eruption, and at the same time lessens the violence and danger of the disease. Our general plan of treatment is accordingly founded upon this principle, to diminish the febrile action of the earlier stages by the general application of the antiphlogistic plan, especially by purgatives and by external cold, and in some cases, where the inflammatory tendency is considerable, by blood-letting. In the distinct variety this may be regarded as comprehending the whole of the treatment; for it would appear, that all direct attempts to act upon the eruption, except so far as we can subdue the fever, are at least useless, if not positively injurious. Tonics and stimulants are seldom indicated, or only in consequence of some unusual occurrence; and when the disease has run through its course, the powers of the constitution soon return to their accustomed standard.

In the confluent Small-pox we have a much more formidable disease to combat, and one which, unfortunately, but too often baffles all our endeavours. From its very commencement it exhibits symptoms that have so much of the typhous appearance, as almost to deter us from the use of any active antiphlogistic treatment, and even purgatives and cool air appear to produce a dangerous shock to the oppressed and languid powers of life. Still, however, they afford the only rational means of relief; but they must be pursued with caution, and under the constant inspection of some person who is well qualified to judge of their effects. The circumstance which renders the practice, in this variety of the complaint, so critical, is, that when, from any cause, the eruption suddenly disappears—an effect which sometimes ensues from the sudden application of cold to the surface, or from the operation of a brisk purgative, the vital powers become suddenly oppressed in so great a degree, as to threaten the immediate extinction of life. When we suspect this to be the case, we are to apply external warmth, and to administer moderate doses of stimulants; but this is to be done with caution, lest in this way we exasperate the violence of the febrile action. Sometimes, without any obvious cause, this deficiency of action ensues, when we are immediately to have recourse to the same means with those mentioned above. When the symptoms of variola assume the decided typhous type, and especially in the secondary fever, it has been generally conceived that wine, bark, and other stimulants and tonics, are the appropriate remedies. We doubt how far this can be depended upon as a general mode of treatment; but we apprehend that we are, in these cases, to proceed very much upon the same plan which has been already recommended in the latter stages of other malignant fevers, of prescribing very much to obviate or palliate particular symptoms; bearing in mind, that we have to contend, on the one hand, with a tendency to febrile excitement, and, on the other, with the state of exhaustion, which generally succeeds the former, when it has been violent and long protracted. There is often, in confluent Small-pox, a state of restlessnes, or extreme agitation, which is found to be alleviated by opium; and although we do not expect any benefit to be derived from sudorifics, we conceive that gentle diaphoretics are often productive of great relief to the sensations, and, by removing a source of irritation, conspire with opiates in procuring sleep. One of the most distressing effects of confluent Small-pox, is the injury which it leaves to the constitution generally, or to particular organs, of which the eyes are the most apt to suffer, so as not unfrequently to produce the complete loss of sight.

Sect. XX. *Vaccinia. Cow-Pox.*

The singular affection of Vaccinia has become an object of great attention, in consequence of the remarkable property which it possesses, of protecting the constitution from the attacks of Variola; and as it is, under all its forms, a comparatively mild disease, and likewise possesses the peculiar advantage of being communicated only by absolute contact, it forms the means of securing the individual, without spreading any dangerous infection through the community at large.

The characteristics of Vaccinia are to produce a vesicle of a circular form, with a depression in the centre, which makes its appearance in three or four days after the insertion of the matter under the cuticle. On the eighth day it becomes filled with a transparent watery lymph; which, about the tenth or eleventh, is converted into a dark coloured scab, and falls off, leaving a permanent mark on the part. Although the constitution receives so important a change by the disease, yet the general febrile affection is almost too slight to be observable; and, except in some extraordinary cases, the only medical treatment which it requires is the exhibition of a purgative at its termination. It was not to be expected, that so great an innovation in practice should be generally received without opposition; but, whatever may have been the motives of the parties concerned, the results of all the controversies that have been carried on have been very fortunate; for we have, by their means, had an opportunity of viewing the subject under every possible form, so as to arrive at a degree of well-grounded confidence, which could not otherwise have been obtained. It is admitted, that there are cases where Small-pox has succeeded to Cow-pox; but they are of very rare occurrence; perhaps not more so than a second attack of Small-pox, of which a few unequivocal cases are upon record: and it has, moreover, appeared, that the Small-pox which follows Cow-pox, has had its virulence so mitigated, as to be nearly without danger. We may farther add, that the accounts which were, at one period, so industriously propagated, of loathsome eruptions succeeding to Cow-pox, are now considered to be altogether without foundation.

Varicella, or Chicken-pox, is a complaint which exhibits the characters of a true Exanthema, but is so mild in its symptoms as scarcely ever to become the subject of medical treatment; and is only worthy of our notice, as being sometimes confounded with slight cases of Small-pox, and thus given rise to the idea of a second attack of Variola, or of its occurrence after Vaccinia. Varicella may, however, be distinguished from Small-pox by the period of its successive stages, which are altogether much shorter, not exceeding, in the whole, five or six days, and in the nature of the fluid contained in the vesicles, which is watery and nearly transparent, never assuming the purulent appearance.

Sect. XXI. *Scarlatina. Scarlet Fever.*

Considerable difference of opinion has arisen on the subject of this disease, whether all the forms of it belong to one affection, of which they are merely varieties; whether the fever be symptomatic of the inflammation of the throat, or whether it more properly belongs to the Exanthemata, where the fever and the eruption are both essential parts of the disease. This latter we believe to be the correct view of the subject; and we farther conceive, that all the various forms which Scarlet fever assumes are simply varieties, like those which we noticed in Small-pox, principally depending upon its degree of virulence.

The disease consists of a fever, which usually inclines to the inflammatory type. About the fourth day the face becomes swelled, and large patches of a red efflorescence appear, which gradually spread over a considerable portion of the surface. These, in two or three days, terminate in an exfoliation of small branny scales; a degree of anasarca frequently supervenes, on the decline of the other symptoms. This may be considered as the simple form of the complaint, when it exists in a mild degree; but, in its more violent state, all the symptoms are aggravated. The fever, from the commencement, has more of the typhoid type; the redness is more considerable; and, at the same time, the deglutition and the respiration are affected, and an inflammation is observed in the internal fauces. These parts, when first affected, exhibit a deep red colour; they are quickly covered with a brownish fur; and vesicles appear, which assume a purulent aspect, and finally degenerate into gangrenous sloughs. Great general debility then comes on; and the patient is carried off in a few days, with all the symptoms of complete exhaustion, and an apparent tendency in the constituents of the body to fall into a state of decomposition.

The disease, when most acute, comes to its acmé in five or six days, and requires an equal period to pass through the remaining stages. When it terminates fatally, the event usually occurs from the sixth to the tenth day; but it not unfrequently happens that the patient survives long after this period, and is finally destroyed, as it appears, from the effects of mere weakness. It might appear highly improbable that so severe an affection as that of the throat should be only, as it were, an incidental part of the disease; yet this seems to be the case; for, in the same epidemic, we have some persons in whom the throat is severely affected, and others where it is not so, although, as was observed with respect to the two varieties of Small-pox, every epidemic has its characteristic form, or prevailing tendency, in which one variety is met with more frequently than the other.

We are quite unacquainted with the nature of the connexion which the different parts of the complaint bear to each other, but we have learned the important fact, that they all have an exact relation to the nature or degree of the fever; and hence we deduce the practical consequence, that whatever means tend to subdue the fever will mitigate all the subsequent symptoms. There is no complaint in which the cold affusion proves so valuable a remedy as in Scarlatina. The temperature of the body seems to be more increased in this complaint than in any other febrile affection; and we find that this method of applying cold not only effectually reduces the heat, but materially diminishes the virulence of the disease, so as, in a great measure, to ward off the danger which arises from its putrid tendency. If, however, these remedies fail in their desired effect, or if we have not had an opportunity of seeing the patient in the early period of the disease, we have unfortunately to struggle with a succession of symptoms, which it is commonly beyond our power to remove. Bark and wine were, at one time, regarded as essential to the cure; but, we apprehend, rather from theoretical opinions, than from any experience of their good effects. Emetics have been strongly recommended, as well as acids and acrid stimulants, together with topical remedies, such as have been supposed were adapted to subdue the tendency to putrefaction, or to counteract the effect of the putrid matter that was discharged from the ulcers. Some benefit appears to have been gained by the use of stimulating gargles; but, in general, we shall find the severe form of the scarlatina, when it arrives at its later stages, to be one of the most untractable and formidable of all complaints. Stimulants and excitants may be given, as affording the only prospect of relief; and all circumstances are to be carefully obviated, that may, in any way, exhaust the languid powers of the patient, or produce a degree of morbid excitement. As the disease is extremely contagious, the same means of prevention are to be resorted to, as we recommended above in other analogous cases; and we have reason to think that the acid fumigations possess the same power of extinguishing or decomposing the contagion of Scarlatina as of typhus. Some difference of opinion has arisen respecting the question, whether Scarlatina can occur twice in the same person? We believe that it cannot do so in any considerable degree; yet it would appear, that the same individual is subject to repeated attacks of a slight local affection of the throat, and even to a degree of fever, provided he is much about the person of the sick, or immediately exposed to the sources of infection.

Sect. XXII. *Rubeola. Measles.*

The only remaining affection of the proper exanthematous kind is the Measles, a disease which is characterized by a fever of the inflammatory type, together with all the symptoms of a violent catarrh, and particularly by a copious discharge of watery humour from the eyes and nose. About the fourth day an eruption of small red points makes its appearance all over the surface of the body, which, after continuing three or four days, disappears without proceeding to suppuration, and is succeeded by the desquamation of the cuticle, in the form of small branny scales; the fever and catarrhal affection disappear about the same period. A very remarkable circumstance in the history of medicine is, that Scarlatina and Rubeola were not properly distinguished from each other until about the commencement of the last century, a circumstance which has led some writers to suppose that Scarlatina is entirely a disease of modern times, and that it did not exist until just previous to that period, in which it was first noticed as a distinct affection from Rubeola; but, upon the whole, we do not see sufficient evidence for this opinion. The diagnosis between the two complaints, in mild cases, is perhaps not always very easy, nor is it very important; but whenever they are either of them severe, no difficulty occurs in the discrimination, and it then becomes a very important practical point, as they are of an opposite tendency, and require very different modes of treatment.

The measles, in every part of their course, exhibit an inflammatory aspect, and indicate the antiphlogistic regimen. Unless the constitution be predisposed to pulmonary affections, the disease be unusually severe, occur in very early infancy, or under some peculiarly disadvantageous circumstances, Rubeola is not a very dangerous complaint, but it is one in which it is necessary to act, in the earlier stages, with promptness and vigour, as, if this opportunity be suffered to pass by, our remedies will be far less efficacious, or perhaps altogether inapplicable. The degree to which we are to carry the antiphlogistic system must be determined by the circumstances of the individual case, by the character of the prevailing epidemic, the season of the year, and other collateral circumstances. Bleeding, either general or local, will be often necessary; purgatives are always proper, and we are carefully to maintain a regulated temperature, avoiding the extremes of heat, but shunning the direct application of cold. Any circumstance which may cause the sudden disappearance of the eruption is always to be guarded against, as indicating a dangerous state of inaction in the sanguiferous system; and, should it occur, it must be removed by the means that were pointed out with respect to Small pox. The cough is sometimes so troublesome a symptom as to require particular attention; but, for the most part, whatever relieves the febrile state will relieve the affections of the chest. Attempts have been made to produce the disease by inoculation, but it does not appear that any great benefit is obtained, or that the disease, when communicated in this way, is mitigated in the same manner as it is in Small-pox.

Sect. XXIII. *Erysipelas.*

There are two other diseases, that are usually placed by systematic writers among the exanthemata, although it would appear without any sufficient claim to this situation, Urticaria or Nettle-rash, and Pemphigus. They both consist of peculiar eruptions, the former, as its name indicates, very much resembling the sting of a nettle, the latter consisting of large irregular vesicles. A degree of fever attends them, but it is uncertain what relation the topical bears to the general affection; and as they are diseases not very well characterized, and often so slight as not to become subjects of medical treatment, we have not much accurate information respecting them. Urticaria is generally conceived to depend upon a peculiar state of the stomach and bowels; and Pemphigus appears to be symptomatic of, or consequent to, a general morbid condition of the system. Their treatment chiefly consists in removing any obvious sources of irritation, and in restoring the healthy state of the digestive organs.

We have placed Erysipelas as an appendage to the genus Exanthema, because, although wanting some of its characteristic circumstances, it seems to be more allied to it than to any other class of diseases. It consists of a fever, which is succeeded, at a certain period, by a cutaneous affection; the fever is of the inflammatory type, is attended with a degree of drowsiness, or even sometimes with coma and delirium; the head and face are hot and swelled, and a considerable part of the surface is attacked with an inflammation, which frequently produces large vesications that become filled with a serous fluid; it usually appears on the face or on the extremities. This disease differs materially from the other Exanthemata, in occurring more than once to the same individual; indeed, when a person has been affected by it, he is ever afterwards peculiarly liable to its attacks. Its exciting cause is obscure; it attaches itself to particular constitutions, which, however, it is not easy to characterize, and seems to have some connexion with peculiar states of the atmosphere, as it is epidemic in certain situations, as in hospitals, or other places where numbers of sick are crowded together, and especially patients suffering from wounds or surgical operations. It is doubtful whether it be ever properly contagious; but, upon the whole, the evidence appears to be in favour of its not being so. It has been thought that, when the disease prevails epidemically, as in hospitals, its symptoms differ from those of the cases that occur sporadically, and that in the former instances it assumes altogether a different type, possessing more of the malignant or typhous character; we are inclined, however, to doubt this conclusion, and are more disposed to attribute it to the greater violence of the complaint under these circumstances, in consequence of which its primary symptoms are more highly inflammatory, and are therefore succeeded by a state of greater exhaustion.

Considerable difference of opinion has arisen respecting the treatment of Erysipelas, and especially respecting the question, whether the antiphlogistic plan is to be employed, and whether external cold is admissible; or whether there is the same danger to be apprehended from repelling the inflammation as in some of the proper Exanthemata? Perhaps no general answer can be given to this question, which will apply to all cases; in the first stage of the disease, the antiphlogistic treatment, both general and local, is the one which usually ought to be pursued, but afterwards a medium course seems to be the best; external warmth aggravates the fever, while the feelings of the patient, and the weakness which supervenes, are adverse to the employment of depletion, or of any considerable degree of external cold. General bleeding is often necessary at the commencement; and purgatives, in this, as in all febrile affections, form a very valuable remedy. Although it may appear to be indicated by the symptoms, yet topical bleeding is generally condemned, in consequence of the difficulty which sometimes exists in healing the wounds made by the leeches or the scarificator. Diaphoretics are commonly prescribed; but if they are administered so as to become sudorific, they aggravate the irritation of the surface. Small doses of opiates are often rendered necessary by the restlessness and agitation which attends the disease; and it is for the same cause peculiarly important to avoid all sources of irritation, or to remove them whenever they are present. When the disease terminates fatally, it appears to be from the inflammatory affection being communicated or transferred to the membranes of the brain; it is therefore of great consequence to prevent all those circumstances which might tend to lay the foundation for such a crisis, and to obviate the first appearance of any symptoms which indicate the impending danger.

SECT. XXIV. *Hæmorrhagiæ. Discharges of Blood.*

We now come to the third order of the Parhæmasiæ, the Hæmorrhagies, those diseases that are characterized by a discharge of blood, which is not the consequence of external violence or an obvious breach of the surface. As we have already remarked, there is considerable obscurity respecting the proximate cause of hæmorrhage; but it may be stated to consist essentially in an irregular distribution of the blood, or a disposition of it to accumulate in certain parts of the sanguiferous system. It has been usual to divide hæmorrhagies into active and passive, as supposed to depend upon the relative degree of action in the vessels; and there seems to be a real foundation for this distinction, whatever may be our opinion concerning the immediate cause which gives rise to the two states. We do not presume to clear up this difficulty, but we conceive that there is sufficient ground for the opinion, that the former originates more particularly in some derangement of the arterial, and the latter in the venous part of the circulation. Upon this principle we have arranged hæmorrhagies under the two genera of arteriosæ and venosæ, an arrangement which we think may be usefully adhered to, both for the purpose of elucidating our theory and directing our practice; although at the same time it is admitted, that there are certain affections which it may be difficult to refer to their proper class, or that, under different circumstances, a discharge of blood may occur from the same part, which is at one time arterial, and at another venous. To the first genus we may refer Epistaxis, Hæmoptysis, and Menorrhagia, or the discharges of blood from the nose, the lungs, and the uterus; to the latter genus, the discharges of blood from the stomach, the intestines, the hæmorrhoidal vessels, and the bladder, and that peculiar affection of the skin termed Petechiæ. We have added, as appendages to the venous hæmorrhagies, the discharges of blood from the liver and the mouth, although it is probable that they are, in almost all cases, symptomatic affections.

Arterial Hæmorrhagies. Epistaxis, Bleeding of the Nose.

Epistaxis, when idiopathic, appears to be always an arterial hæmorrhage; and although, in consequence of its local nature, and the small size of the vessels concerned, compared to the whole extent of the sanguiferous system, it is seldom attended with fever, yet it seems always to be connected with an inflammatory tendency in the constitution, and is often followed by febrile affections, that ultimately prove of serious consequence. We must, however, observe, that blood is sometimes discharged from the nose, which appears to be of venous origin, but in this case it is always symptomatic, and consequent either upon great debility, or upon a tendency to decomposition of the solids, which, as we have had occasion to notice, exists towards the termination of various malignant fevers. Epistaxis is seldom so urgent an affection as to become the subject of medical treatment; it is generally sufficient to avoid the exciting causes, especially all those circumstances that produce an undue force or velocity in the circulation, as external heat, violent exercise, or intemperance in diet. The discharge may generally be restrained without difficulty by the application of external cold to the part, but if it recur frequently, and the state of the body appears to require it, we must have recourse to bleeding, and the other parts of the antiphlogistic regimen. It has been stated that Epistaxis is what has been termed vicarious, that is, the consequence of the ceasing of some other habitual discharge; perhaps this idea is not altogether without foundation, although we apprehend that it has been carried to a very extravagant length, in consequence of a false theory which prevailed on the subject; it may, however, be necessary to bear in mind the possibility of this occurrence, and to regulate our treatment accordingly.

SECT. XXV. *Hæmoptysis. Spitting of blood.*

All the remarks that we have made respecting Epistaxis will apply to Hæmoptysis, making allowance only for the greater size of the organ, and the function which it exercises giving a much greater degree of importance to any of its affections, and necessarily producing a much greater disturbance in the animal economy. The discharge of blood from the lungs seldom occurs, except in persons of the sanguine temperament, and in them is commonly the immediate consequence of some circumstance which excites the part to undue action, and produces an unusual determination of blood to it. The disease does not appear to be essentially connected with fever, and it often exists independently of the febrile state; but when it is severe, and frequently recurs, the symptoms of fever are generally excited, and these, in their turn, appear to aggravate the complaint. If the patient be not predisposed to pthisis by hereditary constitution, there is nothing in the nature of the disease which should necessarily render it of a fatal tendency; but it so frequently happens that it is connected with a phthisical disposition, as always to become the subject of great alarm.

Its cure consists, perhaps, more in carefully abstaining from all the exciting causes than in any very active practice. The quantity of blood that is lost by the discharge itself commonly renders bleeding unnecessary, and even purgatives, which we have so generally recommended in other affections of a febrile tendency, are sometimes scarcely admissible, in consequence of the irritation which is excited by their operation. Perfect rest, both of body and mind, abstinence, and an equable temperature, are perhaps the best remedies for Hæmoptysis; acids, especially the sulphuric, and various neutral salts, have been recommended, but we apprehend that the recommendation has originated from a false theory; and we doubt the efficacy of the practice. In certain cases of Hæmoptysis, where the circulation is at the same time, weak and quick, digitalis has been prescribed, and apparently with success: it must, however, be given in small doses, and its effects assiduously watched, as an overdose would produce a state of torpor, which might prove dangerous, both from its direct and its indirect effects. If the disease be attended with cough, we must employ those palliatives by which this affection is usually relieved, and if there be pain in the chest, blisters, or perhaps the topical detraction of blood will be necessary. In this complaint we are almost restricted from one of the most powerful means of restraining hæmorrhage, the application of external cold, in consequence of the apprehension that such a practice might produce Catarrh, or inflammation of the chest, which, under these circumstances, must be regarded as a very unfavorable circumstance.

Sect. XXVI. *Menorrhagia.*

Whatever may be our opinion respecting the nature of the menstrual discharge, or the use which it serves in the animal economy, we can have little doubt, that when it exists in excessive quantity, it is generally of that kind which we have termed arterial. It is generally attended with pain in the back and loins, and, when it has continued for any length of time, produces a febrile condition of the system, as manifested by the state of the pulse, and the other functions immediately connected with the circulation. The principal danger of Menorrhagia depends upon the immediate loss of blood, which is often so considerable as to reduce the vital actions to a very alarming state of debility; but it may be observed that, unless it arises from some structural disease of the organ, or is connected with pregnancy or parturition, when it becomes a symptomatic affection, it may usually be restrained by the proper application of remedies.—These are both general and local; the latter are employed to remove the urgent symptoms, and the former to prevent their recurrence.

In stopping hæmorrhage, the immediate object which we have in view is, to produce a coagulum at the mouths of the bleeding vessels, which, in this case, is principally to be accomplished by the topical application of cold. This, partly by its mechanical astringent operation, and partly by its sedative action on the vital powers, seems to diminish the flow of blood along the capillary arteries, and thus admits of the coagulation of the fluid which lies near their termination. Perfect rest, abstinence, and the means which were recommended in the other external hæmorrhages, are to be pursued in this complaint; and, in the same manner, we may employ the lancet, or may administer digitalis, where they seem to be indicated. There is often a degree of restlessness in this complaint which renders opium necesssary. We generally find that acids and neutral salts are prescribed, upon the principle of their being refrigerant; but this effect we are disposed to regard as altogether hypothetical.—The former, at least the citric acid, may be useful in quenching thirst; but the latter we conceive to be always injurious. Astringents and tonics of various kinds have been administered in Menorrhagia, with a view of securing the system against its recurrence. We are of opinion, that it is impossible to produce any astringent effect upon an individual organ through the medium of the stomach; and with respect to tonics, we may observe that their operation is of a critical nature. Perhaps, when the system has been much exhausted by the violence of the complaint, or where copious bleeding has been thought necessary to repress it, such remedies may be indicated; but we must bear in mind, that their effect is ultimately to produce that state of the system which will tend to lay the foundation for the return of the complaint. In most cases, a suitable attention to diet, and to those circumstances which are calculated to establish the healthy action of the digestive organs, will be found sufficient to recruit the system, and is the safer plan of proceeding. We think it may be questioned, how far there is ever an idiopathic Menorrhagia, which proceeds from absolute weakness of the part, although such a state is generally described by systematic writers; for it must be observed, that even where there is a general languor of the circulation, still a relative state of activity may prevail in the uterine system. If, however, such a state really exist, the stimulating plan would be improper, or, at least, of doubtful effect, notwithstanding it might appear to be indicated by the state of the constitution. We must abstain from depletion, or employ it with great caution, and are to trust to topical remedies, with the assiduous employment of those means which may confirm the general health without increasing the activity of the circulation.

Sect. XXVII. *Venous hæmorrhagies. Hæmorrhois, Piles.*

Although, considered either in a practical or a theoretical point of view, there seems no reason to doubt of the actual existence of venous, as distinct from that of arterial hæmorrhagies; yet they appear, in most cases, to be rather symptomatic than idiopathic affections, being either consequential upon some other disease, or indicating a structural derangement in the organ from which they proceed. This remark will, we apprehend, apply to the discharges of blood from the stomach, the intestines, the liver, and the bladder, which are, for the most part, either the effect of previous inflammation of these parts, or of actual disease in them, by which their mechanical texture is obviously deranged. The only means of relief, therefore, is to remove the morbid condition on which the discharge depends, when this can be accomplished; an object, however, which it is too frequently beyond our power to effect. Various palliative remedies have been employed in these cases, but we conceive without much prospect of relief; depletion is not indicated by the state of the system at large, nor do we apprehend that any benefit can be expected from the usual routine of astringents and tonics. Mild purgatives are useful, both from their local and their general effect, and opium may be given to allay irritation and to ease pain; but beyond these we have little to trust to, except the assiduous application of all those means which strengthen the digestive organs, and through their means tend to establish the general health.

There is, however, one of the venous hæmorrhagies which is to be regarded as an idiopathic disease, and which admits of a more direct and decisive treatment, hæmorrhois, or piles, consisting of a discharge of blood from the hæmorrhoidal veins. This disease has excit-

-ed a considerable share of attention, as appearing to coincide with the pathological hypothesis of the Stahlians, respecting the salutary efforts of the intelligent superintending principle, or *anima*. It was supposed that these veins afforded a kind of outlet for the superfluous fluids, when the sanguiferous system was oppressed with too large a quantity of blood, being analogous to the menstrual evacuation of the female, of which this was supposed to be the prime object. We have, however, no hesitation in asserting, that the facts upon which this hypothesis was built were much exaggerated, and that when we view the complaint without prejudice, we shall find it to be, like many others, in a certain degree useful in restoring the balance of the circulation, when it has been deranged by various circumstances, but, like them, always to be regarded as a disease which we must attempt to remove, and which, if suffered to proceed without restraint, lays the foundation for much future inconvenience.

We shall not in this place inquire into the causes which tend to produce congestion in this particular set of vessels; it will be sufficient to remark, that in certain constitutions, and at certain periods of life, the veins about the termination of the intestinal canal are liable to become distended with blood, that they are occasionally ruptured, and discharge their contents, and produce painful and even dangerous abscesses in the neighbouring cellular substance. When the veins are become turgid, it is necessary that they should be evacuated; and it is still more desirable that the turgescence should, if possible, be prevented from taking place. As the disease, although of a local nature, generally depends upon a constitutional cause, we are to use the most effectual means for reducing the plethoric state of the sanguiferous system; for this purpose the antiphlogistic plan must be employed, but rather in its passive than in its active form, for although bleeding and other depletions may be occasionally proper, we are to expect more permanent benefit from a temperate diet, a due proportion of exercise, and only a moderate indulgence in sleep. When there is much inflammation of the parts, leeches are often necessary; and when the discharge is very profuse, we may apply cold and astringents; mild purgatives are also indicated, both from their general and their local effect; and an opinion has very generally prevailed in favour of there being something peculiarly soothing in the operation of sulphur; we frequently find opium necessary to relieve the pain, which is often very severe. When these means have been neglected, or are found ineffectual, surgical assistance is required to remove the tumours, and to heal the ulcers that are occasionally formed; but these operations belong to a different department of the art. Although we do not admit the correctness of the hypothesis which regards Hæmorrhois as a salutary effort of nature, yet we conceive that where the system has been long habituated to such a discharge, if it be suddenly stopped, and no means of prevention be employed, bad effects may be the result. These, however, are easily obviated by using the necessary remedies against the plethoric state, which is then liable to be induced; perhaps general bleeding may be required, as well as purgatives, but we are to rely more upon exercise and temperance.

Of the two remaining diseases, which we have placed in this genus, Stomacace and Purpura, the first may be always regarded as a symptomatic affection, whether existing in the acute form, as we observe it in infants, connected with the disease which is popularly called Thrush, or in that more chronic state, appearing in connexion with Scurvy, or attacking individuals who have suffered from a long residence in hot climates. In both cases the cure depends upon restoring the healthy action of the alimentary canal, and the organs immediately concerned in the function of digestion.

Purpura is likewise, at least for the most part, merely symptomatic, appearing in the later stages of malignant fever, more especially in those where the component parts of the body seem to have a tendency to decomposition. Some cases, however, have occurred, where Purpura has existed without a proportionable degree of the febrile state, or indeed where this has been altogether absent, but they are involved in considerable obscurity; and we have little certain information respecting either their nature, or their immediate exciting cause. The same uncertainty also regards the cure of the idiopathic Purpura; for while we are told from high authority, that it is relieved by tonics, and especially by the mineral acids, we have equally respectable evidence in favour of blood-letting. Fortunately the disease is of rare occurrence, and therefore whatever regards either its cause or its cure, may be considered more in the light of a question of curious speculation, than of any great practical utility.

CHAP. II.

Neuroses. Primary Diseases of the Nervous System.

We now come to the Neuroses, the second great class of diseases—those depending upon a primary affection of the nervous system. As the phenomena of sensibility are more peculiar, and more unlike the other functions of matter, than even those of the muscular fibre, so its morbid affections are proportionally singular and difficult both to comprehend and to describe. The connexion which the different parts of the nervous system bear to each other, is one of its most remarkable properties, and it is exhibited in a variety of striking examples in its morbid states. We can generally assign to each of the Parhæmasiæ its primary seat, either by means of our sensations, or of some visible change which the part experiences, but in the Neuroses, we have neither of these circumstances to direct us; there is frequently no visible alteration in the structure of the part affected, while our feelings afford but little assistance in informing us of the original situation of the disease. The circumstance which must chiefly direct us in our arrangement of this class, is the degree in which the power exists, whether it be morbidly increased, or morbidly diminished, with relation to the standard of health; to this we have added another division of actions, which are simply irregular, without any regard to the mere quantity of effect produced. These three orders we have denominated, respectively, Erethismi, Astheniæ, and Spasmi.

SECT. I. *Hyperæsthesiæ. Affections depending upon an increased sensibility of the nervous system.*

We have divided the order Erethismus into the two genera of Hyperæsthesiæ and Autalgiæ; the first consisting in increased nervous sensibility, as manifested by the inordinate action of the external senses, or of the organic functions; the latter comprehending those diseases where there is pain in any organ, which, so far as we can judge, depends merely upon a nervous affection of the part. The diseases which seem to belong to the order Erethismus, and to the genus Hyperæsthesia, in particular, are many of them evidently symptomatic, or connected with some other disease, which is the principal object of our attention; yet occasionally, under these circumstances, the state of the nervous system itself becomes necessarily the main point towards which we are to direct our efforts. Thus, one of the most distressing effects in fever is want of sleep, and after we have removed the proximate cause of the disease, this sometimes still continues, and, by its harassing effects, prevents the complete re-establishment of the health. The same remarks apply to all those affections which consist in increased sensibility of the organs of sense, such as a morbidly acute state of the sight, the hearing, &c. or increased sensibility in parts that serve for the exercise of the organic functions, as the stomach and the kidney. For the most part we find them connected with some more general affection, which chiefly claims our notice, although, as we remarked above, they sometimes become the immediate objects of attention under these circumstances; and we must also bear in mind, that there are cases in which they indicate some local affection of the part or organ in which, although symptomatic, they are important, as indicating the existence of the primary affection, or assisting us in ascertaining its nature. Thus, a morbid increase of appetite, which is denominated Bulimia, is sometimes merely a symptom of Diabetes, and can in no degree be relieved by any palliative remedy; while at other times it originates from a disease of the stomach itself, which may be either structural or functional, and will of course acquire its appropriate mode of treatment. In the rapid sketch of the practice of medicine which we propose to offer to our readers, it will not be in our power, nor would it accord with our plan, to examine each of these affections in detail.

With respect to the method of proceeding in their management, the first point is, to ascertain how far the disease is primary or symptomatic; if primary, whether it depends upon a local cause of a mechanical nature, upon a visible alteration of structure, or upon an effect which operates through the medium of the system at large. If they are symptomatic, we inquire whether we are able to remove them by removing the primary disease, or by remedies appropriated to the removal of the nervous affection itself. It is not easy to lay down any general principles of treatment in a class of affections, which are so various in their origin, and depend upon such a diversity of causes. There is scarcely any condition of the system by which they may not be excited; and with respect to individual symptoms, they bear so little relation to their cause, that our judgment must be formed more from the general history of the case, and from a number of circumstances connected with it, than from any train of morbid actions which can be detailed, as constituting the essential character of the disease. The opposite states of plethora and inanition, of excitement, and of quiescence, sometimes produce what appears to be the same complaint, and must of course be combated in the individual cases, at one time by depletion and by sedatives, and at another by nutrients and stimulants. Generally speaking, however, we think that the modern practitioners have leaned too much to the latter class of remedies, biassed by their hypothesis of debility, which they have applied with so little discrimination to such a variety of diseases, and anxious to avoid the errors of the older writers, who ascribed nervous complaints to the affections of a subtile fluid, the existence of which they unfortunately neglected to ascertain before they assumed it as the basis of their pathology. We shall farther remark, that what are styled nervous diseases are, much more frequently than is commonly supposed, symptomatic of derangements of the digestive organs. Some remarkable examples of the effect which peculiar states of the alimentary canal produce upon the brain and nerves, are generally known; of which one of the most important is Hydrocephalus, and we are daily accumulating experience of the same kind, with respect to Epilepsy and various kinds of convulsions, when not proceeding from local or structural causes. Purgatives will therefore be always indicated in the Hyperæsthesiæ, if not by the immediate symptoms, at least as a means which is to be always tried, even although we proceed entirely upon empirical grounds.

After we have duly considered how far depletion may be indicated, and removed all local sources of irritation, we then proceed to the exhibition of sedatives, of which opium may be regarded as the prototype, and that which, for the most part, supersedes all the rest. The method in which this medicine operates, and the immediate effect which it produces, have been the subject of many volumes, and have formed the ground-work of some of the most violent and angry controversies of modern times. We have no space, nor indeed have we any inclination, for entering into these discussions; we shall merely state our opinion, that the operation of opium is primarily upon the nervous system, and that it acts upon it as a sedative. Its agency is equally extensive with the nervous system itself, and it is consequently experienced through the medium of so many organs and functions, that we have seldom an opportunity of witnessing its unmixed sedative powers, without, at the same time, observing some secondary effect, which may diminish, or even entirely counteract the primary operation. Thus, by lessening the sensibility of the intestines, opium tends to produce costiveness, and this retention of the fæcal evacuations may prove a greater source of irritation in certain cases, than the symptom for which the opium was administered. It is principally, perhaps, from this circumstance, that there is no remedy which is more uncertain in its effects than opium; and besides this, different individuals have remarkable idiosyncrasies with respect to it, which often interfere with the best regulated plans of the practitioner, and which cannot possibly be learned, except by a previous knowledge of the individual constitution of the patient.

Opium, when given in too large a dose, in an improper state of the stomach, or indeed to certain individuals under all circumstances, produces effects which are very similar to those of the vegetable poisons; and, on this account, it has always been a favourite subject of inquiry to discover a medicine which might possess the mere sedative effect of opium, without its deleterious properties. Hyosciamus, hop, the extract of lettuce, and other substances, have been proposed; but it may be doubted, whether every benefit may not be gained by a sufficient reduction of the dose of the opium.

Various preparations of opium have also been tried with the same intention; and upon one of these, called the black drop, in which the medicine is combined with a strong vegetable acid, great commendations have been bestowed from sources of very high respectability.

Sect. II. *Hydrophobia. Canine Madness.*

Notwithstanding the acknowledged obscurity which exists respecting the nature of this disease, we do not hesitate to place it in the genus Hyperæsthesia, as we think that the only consistent and probable hypothesis of its pathology proceeds upon the supposition of its originating in an increased sensibility of the nervous system. The exciting cause is well known to be a specific contagion, communicated by the bite of a rabid animal, and it appears to be always produced by means of the saliva being conveyed through the absorbents into the circulation. We conceive that the disease never originates in the human species from any other cause, although certain symptoms, in some measure resembling it, may have proceeded from other circumstances, but these we shall be disposed to refer to Hysteria. The question is not so easy to answer, whether Rabies be capable of being produced in other animals besides those of the dog and cat genus, although these, when affected, may communicate it to others, as to the human species, to horses, and to oxen. The disease commences by a peculiar feeling of anxiety, constant agitation, and unaccountable timidity; to these succeed difficulty of breathing, pain and constriction in the region of the stomach, and all over the abdomen, together with the characteristic symptom of an inability to swallow fluids, which soon extends to deglutition generally, and becomes so distressing as to impress the mind with extraordinary terror at the very idea of renewing the attempt. As the disease advances the pulse becomes weak and quick, and a degree of irregular fever supervenes; all the functions which depend upon the nervous power are rendered morbidly acute; there is intolerance of light and sound, the surface becomes exquisitely sensible to the impression of cold air, while towards its termination there is a copious discharge of viscid saliva from the fauces, the mental faculties are deranged, and general convulsions, with a total destruction of all the actions, both animal and organic, are the immediate forerunners of dissolution. The disease is rapid in its course, and most dreadful in its symptoms and aspect, yet its real horrors have been exaggerated by the terror and superstition of those who have witnessed it. The accounts which are met with in the older writers, of the violent fury of the patients, and of their attempts to sieze the by-standers, are probably altogether fictitious; and the dread of water, which has been viewed in so mysterious a light, is found to arise simply from the extreme uneasiness and difficulty which the unhappy sufferer feels in the act of deglutition.

With respect to the event of the disease, we believe it to be always fatal; not only has no cure yet been discovered for it, but it is doubtful whether we are in possession of any plan of treatment, by which its symptoms, when once established, can even be alleviated. The general mode of treatment has been the administration of large quantities of opium, upon the obvious principle of the nervous system being in a state of preternatural excitement; mercury has been given under various forms, but we know of no rational indication, either from theory or experience, which can lead us to expect any benefit from it, while lately very profuse bleeding has been employed, but we fear with a fallacious prospect of success. Besides these, which may be considered as the most powerful remedies that have been had recourse to, a great variety of palliatives, and a still greater number of nostrums, have been made use of; for in proportion to the violence and untractable nature of the disease, so has the credulity of mankind led them to place confidence in the most gross and scandalous impositions. But, although we have had such little success in the cure of Hydrophobia, we have happily in our hands a preventative, which in most cases is of easy application, and of tolerably certain effect; this is the excision of the wounded part, and the complete removal of every portion of the substance, which can be supposed to have been in contact with the saliva of the rabid animal. When, however, this has been neglected, when, from the situation of the wound, it could not be accomplished, or when, from any other cause, the disease makes its appearance, we cannot remain inactive spectators of so much misery, and naturally inquire what plan of treatment promises the least prospect of success, or may seem in any degree calculated to relieve the sufferings of the patient. To this question we are not able to return a satisfactory answer; we do not place the smallest reliance upon any of the numerous specifics that have been proposed, nor do we feel much more hopes from the effect of depletion, from opium, or from mercury. Guided, however, by the faint analogy which presents itself, we know of no treatment which is more promising, and therefore feel justified in beginning with a very copious bleeding, which is to be followed by a powerful mercurial purgative, and, when this has operated, by large doses of opium, combined with an equal quantity of calomel. We think it extremely important that perfect quiet should be enjoined, that all motion should, as much as possible, be avoided; and especially all unnecessary touching or handling of the patient. On this account, we conceive that frictions may be injurious; and indeed we think that any remedy which is merely indifferent, and is not given to promote some definite purpose, ought to be abstained from, as likely to do mischief, from the circumstance of its exciting the patient, or giving him any unnecessary cause for the exertion either of his mental or his corporeal powers.

Sect. III. *Autalgiæ. Painful nervous Affections.*

We have formed our second genus of the order Erethismus of the Autalgiæ, those diseases which depend upon a primary affection of the nervous system, and which are characterized by severe pain and uneasiness in the part affected. These are frequently symptomatic, but we are often unable to perceive any more general complaint to which they may be referred; and even where this is the case, the violence of their symptoms require our attention to be immediately directed to the local affection. The diseases which we shall enumerate under this genus are, Neuralgia, Cephalalgia, Prosophalgia, Otalgia, Odontalgia, Mastodynia, Pleurodyne, Gastrodynia, Arthopuosis, Sciatica, and Pruritus, to which we ought perhaps to add Lumbago. From a view of this list, it will appear that these affections are often attendant upon, or a consequence of inflammation, and sometimes arise from structural derangement; yet we have in some cases the most equivocal evidence, from the effect of remedies, that the disease is seated in the nerves of the part. We particularly refer to that most painful affection Prosophalgia, or, as it is popularly termed, Tic doloureux, where the disease may be clearly traced along the course of a particular nerve, and is at least for a certain period entirely removed by dividing the trunk of the nerve. In order to form a correct judgment of these complaints, it is particularly necessary to make ourselves acquainted with their history and symptoms from the commencement, otherwise there will be danger of our confounding the cause with the effect. In some of them, where the primary derangement is most evidently in the nervous system, we find obvious symptoms of increased action in the blood-vessels to supervene; and it even appears that a more permanent alteration in the structure of an organ may be produced by an affection, which, in the first instance, was simply attached to the nerves of the part. It is difficult to explain the nature of the operation by which a disease of the nerves is converted into one of the sanguiferous or secretory vessels; but we apprehend there can be no doubt of the fact, and we believe that it may be even affected by the mere influence of mental impressions, if they be sufficiently powerful, and steadily directed to the same part.

The cure of the Autalgiæ necessarily depends upon a number of minute circumstances which are connected with the local situation and functions of the organ affected; and in some of them there are certain remedies of a specific nature, which it is not easy to account for upon general principles, of which the use of the oxide of bismuth in simple pain of the stomach may be adduced as an example. In deciding that the disease is either idiopathic, or that it must be made the object of direct medical treatment, we first inquire whether there are any symptoms of inflammation which may render depletion necessary, or the other means by which we subdue the inflammatory action; we then apply blisters, issues, or other stimulating remedies, upon the principle of exciting what is called counter-irritation, proceeding upon a general law of the animal economy, according to which we remove a morbid action, by substituting for it a new, and probably a more considerable one, in some contiguous part, which latter is attended with no dangerous consequence, and which we have it in our power to remove at pleasure. In the Autalgiæ, as well as in the Hyperæsthesiæ, purgatives are generally useful, although perhaps not so universally; and opium, if it does not accomplish a radical cure, is at least one most effectual means for affording temporary relief. It has been observed, that some of the most severe pains to which the human frame is liable, recur at periodical intervals; and it has been found that in these, as in all other periodical diseases, bark, and even arsenic, may be employed with success; this latter remedy, however, we should not be disposed to try, until all other methods had failed; and it should likewise be accompanied by proper evacuations. Of their mode of operation, as well as of the circumstances which tend to give the diseases in question their periodical character, we are totally ignorant, and our practice, in these instances, is entirely empirical.

Sect. IV. *Nervous Fever.*

The second order of the Neuroses is Asthenia, including those diseases which consist in a diminution of the nervous energy; and under this we include three genera, the first of which is simple Nervous fever. We are aware of the apparent incongruity in placing the different kinds of fevers in different classes, and in supposing them to proceed from totally different causes, connected with a different set of functions, more particularly as it must, at the same time, be admitted, that the two diseases slide into each other by almost imperceptible degrees, so that it is often extremely difficult to know into what class any particular case ought to be referred. But, notwithstanding these objections, we are clearly of opinion that certain sporadic cases of fever, as well as certain general epidemics, exhibit symptoms which may be supposed to arise from a primary affection of the nervous system, while the sanguiferous system is but little affected, and that the two fevers are not merely different gradations of the same species of disease, in which the proportion between the symptoms remains the same, while the degree of both is equally diminished. We think it is not difficult to perceive a difference in the exciting cause, as well as in the effect produced; for while contagion is probably the sole cause of the proper Typhus, or putrid fever, the nervous fever never arises from this source, but from mental agitation, from over-fatigue, from complete exhaustion, or from other circumstances which might be expected to act upon the brain and nerves, more than upon the heart and arteries. The symptoms, and general character of the two diseases, when we take the most strongly marked cases, are no less easy to discriminate from each other. In the Nervous fever we do not observe the successive stages which we have in Typhus; there are no marks of oppression or congestion, nor of the subsequent attempt at reaction; but, from the very commencement, there are indications of weakness and irritability, the pulse quick and feeble, the heart little affected, not much thirst or disorder of the alimentary canal, except a less relish for food than ordinary; while, on the contrary, we have delirium, and all that derangement of the sensations, which indicates an irregular action of the brain and nerves, but, at the same time, without any appearance of turgescence in their vessels, or of that oppression which arises from a congestion of the fluids.

In the cure of Nervous fever, we must refer to the same principles which we have laid down with respect to its pathology; we require no general depletion, but we begin from the first with stimulants and excitants, exhibited in moderate doses, and proportioned to the effect which they have in rousing the dormant powers of the system. It is obviously of great importance to remove, if possible, the exciting cause, when it still remains applied, and in the later stages of the disease we must have recourse to stimulants and tonics, and shall find the proper management of the diet a most effectual part of the medical treatment. It is in fevers of this description that wine becomes a valuable remedy, and it is often found more grateful to the stomach than any stimulating compound which we can procure from the apothecary. It would have been fortunate for mankind if its use had been restricted to this disease, and had not been extended, by a false or imperfect analogy, to other affections which it resembles scarcely in any thing but in name.

Sect. V. *Anæsthesiæ.*

The second genus of the Astheniæ, Anæsthesia, is divided into complaints which consist in general debility of the nervous system; defects of the external senses, not depending upon a change in the structure of the organs; and in debility of the organic functions. The two first of these subdivisions may, almost all of them, be considered as symptomatic of some more general affection; the latter, under which we include Aphonia, Dysphagia, Anorexia, Dysuria, and Anaphrodisia, are not unfrequently primary, although at other times, like the former, only symptomatic. They depend occasionally upon an obvious change of mechanical structure, when they properly belong to a different part of the nosological system, and must be removed by mechanical remedies, as is frequently the case with Dysphagia and Dysuria. When, however, they are merely nervous affections, the cure is to be accomplished upon the same general principles which were detailed above, regard being always had to the local situation and specific functions of the part.

Sect. VI. *Apoplexia. Apoplexy.*

The third genus of Asthenia is formed by the Dyscinesiæ, those diseases which essentially consist in a loss or diminution of the power of voluntary motion, arising, for the most part, from an organic derangement of the brain; we include under it the species Apoplexia, Paralysis, Hydrocephalus, and Lethargus.

Apoplexy is characterized by a sudden abolition, or considerable diminution of both the external and the internal senses, and of the power over the muscles of voluntary motion, while the circulation and the organic functions continue to perform their actions. The pulse is, however, slow and oppressed, and the inspiration performed after long intervals, and accompanied by stertor, while the countenance is flushed, and the sensibility so much impaired, that the patient is unconscious of the most powerful impressions that can be made upon him. The immediate cause of Apoplexy appears to be, almost in every instance, the effusion of blood or serum on the surface of the brain, or into some of its cavities, which may be supposed to compress this organ, and thus prevent it from performing its due functions. Occasionally, however, we observe persons to be attacked with symptoms which have every claim to be considered as apoplectic, where, from the complete and very speedy recovery that takes place, we are unavoidably led to conclude that no considerable injury has occurred to the structure of the brain, an opinion which has been confirmed by some cases of dissection, although it is obvious that such opportunities can only be of accidental occurrence, where the patient has died from some other cause soon after his recovery from the Apoplexy. The state of insensibility which is occasioned by complete intoxication is very similar to Apoplexy, so much so, that except from the previous history of the case, from the length of time which it continues, and from the odour exhaled by the breath, we have frequently great difficulty in discriminating between these affections, although arising from such very different causes, and producing such different ultimate effects upon the system. Persons who have suffered from Apoplexy are observed to be of a peculiar temperament or bodily conformation; they are generally corpulent, with short necks, and large heads, and exhibit various indications of a torpid state of the blood-vessels, attended, at the same time, with considerable force of the circulation, and firmness in the texture of the components of the body. According to the nature of the fluid which is effused, whether it be entire blood or only serum, the disease has been divided into the two varieties of sanguineous and serous, and it seems that this division has an actual existence, but we doubt much whether we have any certain means of ascertaining them before death from the symptoms of the case.

The proximate cause of the disease is supposed to be a congestion of blood in the vessels of the brain, generally terminating in effusion; it has been a controverted question, whether a proper Apoplexy can be produced by the mere accumulation of blood in the vessels, without absolute effusion taking place, a question which we should be disposed to answer in the affirmative, although it is difficult to prove the point by a reference to dissection, because, when there is no actual rupture of the vessels, recovery may be supposed generally to take place, so as not to admit of our examination. The exciting causes of Apoplexy are various, but may, for the most part, be referred to those circumstances which increase the impetus of the blood through the arteries of the head, or retard its egress from them. Violent exercise, sudden fits of passion, severe mental exertions of all kinds, certain postures of the body, the direct application of the sun's rays to the head, blows, or mechanical injuries of the part, and especially intemperance in eating or drinking, are among the most frequent causes assigned for Apoplexy, and may be obviously accounted for upon the above principle. There are, however, other causes, such as narcotic poisons, metallic fumes of various kinds, some of the unrespirable gases, especially the carbonic acid, and intense cold, which, although they induce the symptoms of Apoplexy, may perhaps be supposed to act upon the nervous system generally, by diminishing the sensibility of all its parts, rather than by producing any local affection upon the brain in particular. After a severe attack of Apoplexy, except it arise from some obvious external cause, the functions, both of the body and the mind, seldom regain their former vigour, and, for the most part, either one side of the body is left without motion, constituting what has been termed Hemiplegia, or the whole of the voluntary motions and mental powers continue in a very imperfect and enfeebled state. We have sometimes curious instances of the loss of individual faculties, as the memory of names, of dates, or of places, and occasionally of a particular language: such cases have given rise to many pathological and metaphysical speculations, but these do not hitherto appear to have been sanctioned by the results of our anatomical examinations.

The cure of Apoplexy consists first in removing the exciting cause of the disease, should this still remain applied, and afterwards in endeavouring to relieve the congestion of the vessels. This last is attempted by large bleedings, which are thought to be more effectual when the vessels near the head are opened, such as the jugular vein or the temporal artery; we may also take blood from the cutaneous vessels by the scarificator or by leeches, and afterwards apply large blisters to the neck; along with these drastic purgatives are to be given, so as to procure a free evacuation from the bowels. Where the disease appears to have been immediately produced by repletion of the stomach, or by any noxious substance received into it, an emetic will be proper, but in other cases vomiting is thought to be rather injurious, or at least does not seem to have any claim to be considered as a remedy of general application. When depletion has been carried as far as has been thought necessary, or as the state of the patient will justify, little efficient treatment remains to be employed; stimulants must at first be used with great caution, as any degree of over-excitement might bring back the original complaint; the longer the disease has continued the more freely they may be given; but it must at the same time be confessed, that we can have less expectation of benefit from them. Upon the whole, if the complaint be not relieved, either by the efforts of nature, or by the operation of our remedies, soon after its first invasion, we are not to hope for much advantage from any thing that can be done in future, but must confine ourselves to relieving particular symptoms, and soothing the helpless condition of the patient, by an attention to a variety of minute circumstances, for which no general rules can be prescribed.

Sect. VII. *Paralysis. Palsy.*

Paralysis may be regarded as a partial Apoplexy, and is, in most instances, the sequel of that disease, when it does not terminate fatally. The two diseases originate from the same causes, and commence nearly with the same symptoms, in the most severe kind of Palsy; but besides these, we have partial Paralysis, sometimes of a single limb, or even of a single muscle, which proceeds entirely from some local injury of the nerves of the part. We have also another variety of Palsy, in which the affection is general, but less violent, where there is no sudden seizure, and where the loss of sensation and motion is not complete in any one part, but where there is a degree of weakness over the whole body, and especially in the voluntary muscles, accompanied by tremor, partial convulsions, numbness, and frequently by a general wasting of the part. This kind of Paralysis is the consequence of the excessive use of opium, or a too free indulgence in ardent spirits, and is occasionally observed to come on in old age without any assignable exciting cause. In the more severe cases of Palsy, and in those that are left after an apoplectic attack, we usually find that exactly one half of the body is affected, constituting the variety of Hemiplegia; and upon dissection we find, in most of these cases, that the injury to the brain is on the opposite side to that of the paralytic limbs, a fact which has been much employed by those who have speculated upon the pathology of the nervous system. Another variety of Palsy is Paraplegia, where the diseased is separated from the sound part of the body by a transverse section; this proceeds, in almost all cases, from an injury to the spine, and of course the extent of the disease depends upon the part in which the spine is affected.

Where the Paralysis occurs in its violent form, or is the sequel of Apoplexy, its treatment must, in every respect, coincide with what was recommended above for this complaint: we must begin with copious depletion of the sanguiferous system, then administer active purgatives, apply blisters, and gradually have recourse to stimulants. But, in many cases, the accession of Palsy does not indicate that state of the blood-vessels, which leads us to suppose that bleeding is necessary; and although, perhaps, purgatives are always proper, we place our chief reliance upon the stimulating plan, after we have done all that lies in our power to remove the exciting cause. The stimulants that have been employed in Palsy, both general and local, are very numerous; the choice must depend upon circumstances connected with the nature of the constitution of the patient and the part affected. They consist both of various articles of the materia medica, and of different mechanical applications; among the former, we may enumerate ether, and spirituous compounds, lytta, oleum terebinthinæ, ammonia, sinapis, the warm essential oils, and the whole class of vesicants, and rubifacients. Among the more efficacious of the mechanical applications, is friction in various forms, hot fomentations, electricity, and galvanism, a remedy which, however, has not answered the high expectations that were formed respecting it; the natural thermal springs are had recourse to with benefit in the later stages of Palsy.

It would be incompatible with our object to point out the means employed for removing the various local causes of Palsy; but there is one that is connected with diseases of the spine, which forms so important an object of our attention, as to require being distinctly noticed. When the disease occurs spontaneously, it has been conceived to originate from a scrofulous tendency in the constitution, and it must therefore be combated by all those means which are supposed to be useful in counteracting this tendency. Practitioners, however, are but too well aware of the little benefit that is to be derived from the most approved of these means, and generally all that lies in our power is to endeavour to remove the local complaint, and this has been usually attempted by the application of caustic issues near the part affected. A new plan of treatment has been lately proposed, in which, instead of issues, the patient is strictly confined, for a great length of time, to the horizontal posture. When we consider the nature of the affection, and especially when we perceive the ravages which it commits in the structure of the bones, we can scarcely imagine how mere rest, although a powerful adjunct, can alone perform a cure, and we are led to conjecture, that in those cases where this plan has been successful, the symptoms depended simply upon weakness, or a loss of voluntary power, arising from a nervous affection, but without any structural disease. In Palsy of long continuance, where the original cause of the disease is removed, and where the structure of the part is irremediably injured, it has been found of great importance for the patient to use as much voluntary exertion as possible in the affected muscles, and in this way the healthy action has been restored in parts which were previously almost quite useless.

Sect. VIII. *Hydrocephalus. Water in the Head.*

We have placed this disease in the genus Dyscinesia, although it is in fact a species of dropsy, because both its symptoms and its treatment connect it more with the primary diseases of the nervous system, than with those of any other part of the animal economy. The origin of this disease, and its predisposing causes, are obscure: it affords a remarkable instance of the existence of a peculiar train of symptoms, indicating an affection of a part remote from that whence they might naturally be supposed to proceed, and of the sympathy between two parts, not related to each other by their local situation, or by any obvious action of their functions. The disease, when it exists under its usual form, commences with fever, violent pain of the head, characterized by an acute darting sensation, which is generally felt in the temples or across the forehead; great sensibility to light and noise, extreme agitation and restlessness, with the expression of sudden paroxysms of severe suffering; along with these symptoms there is great derangement of the digestive organs, vomiting and obstinate constipation, with a peculiar morbid appearance of the evacuations. After these symptoms have continued, the state of excitement appears to be succeeded by one of oppression; there is a considerable degree of coma and stupor, while the pulse becomes preternaturally slow, the pupils dilated, and the bowels still more torpid. The indications of severe suffering are exchanged for those of insensibility, and at length a complete state of Paralysis supervenes, and announces the near approaches of death. The acute disease is seldom, if ever, found after the age of puberty: it has been supposed, although, as we think, without sufficient foundation, to be connected with a tendency to Scrofula or Rickets; it is, however, hereditary, and therefore may be conceived to attach to some original peculiarity in the structure of the body. Its exciting causes are not well ascertained; for although it may occasionally appear to follow an injury of the head, in most cases we are unable to trace it to any thing of the kind. With respect to its proximate cause, we apprehend it must be regarded as originating in an inflammatory action of the capillaries of the brain, although probably of some specific kind, and that the effusion of the fluid is the consequence of the increased action of the vessels. In what consists the essential difference between Hydrocephalus and Phrenitis is not well ascertained, whether upon a different set of vessels, or upon a different action of the same vessels; the diseases are, however, in all respects very different from each other, both with respect to their symptoms and their treatment. The connexion which we observe between the state of the alimentary canal and the head is difficult to explain; and what increases the difficulty is, that symptoms which very nearly resemble those of Hydrocephalus not unfrequently exist, where it would appear that the head is not actually the seat of disease, and which are referred to the effect of worms. But every thing that respects the existence of worms, or the symptoms which they produce, is very obscure, and is so much involved in empiricism, that we are always at a loss to determine what degree of credit is to be attached to the statements that are made on this subject. Upon the whole, we are disposed to consider the peculiar state of the bowels as partly the cause and partly the effect of the condition of the brain, and, as far as regards the point of practice, whichever is actually the primary disease, the plan of treatment is not materially different.

The cure of Hydrocephalus is to be attempted by diminishing the over-excitement of the vessels of the brain, and by restoring the action of the alimentary canal. The first is to be attempted by blood-letting, which is generally local, and which must be persevered in as far as the strength of the patient, or the other circumstances connected with the case, will admit, but which is seldom effectual, unless it be carried to an extent which would not be justified under less urgent circumstances. Purgatives are to be also administered with steadiness and perseverance, until the evacuations assume a more natural aspect, and it is generally agreed, that they are more effectual when calomel enters into their composition. Along with these, which are our principal means of relief, we apply blisters to the head and neck, with external cold, and likewise give such remedies as may be indicated by the general state of fever, or by any other peculiarly urgent symptoms. These remedies are to be used in the first stage of the complaint: should this be passed by, and the symptoms of effusion manifest themselves, we believe that every means will be unavailing, but still it is our duty to attempt what offers the most probable chance of relief, and among the remedies which have been recommended at this period is mercury, given so as to produce its specific effect upon the system. How far we are still to use blood-letting is a question which must be decided by the symptoms of each individual case, but the assiduous use of purgatives will still be proper; we must, however, be careful, lest, in our eagerness to administer medicines, we aggravate the sufferings of the patient, and, by an ill-directed solicitude, disturb the short remaining period of his existence.

Besides the disease which we have now been describing, which is altogether of a very acute kind, there is a chronic Hydrocephalus, where the disease comes on so slowly as scarcely to produce any general affection of the system. The bones of the skull in these cases gradually give way to the pressure of the fluid effused in the interior parts of the brain, and the head becomes enlarged to a degree which would have been supposed incompatible with the exercise of any of the functions, or indeed with the actual continuance of life. This complaint is irremediable, or, if any relief can be obtained, it must be by hazarding an operation which promises so little advantage, that nothing but the miserable state of existence in which the patient is reduced by the disease could sanction the experiment.*

* Hydrocephalus may most justly be considered an inflammatory affection of the brain. It often approaches very insidiously, having its primary seat not in the membranes, but in the parenchymatous portion of that organ. Like other inflammations seated in soft parts, it is frequently overlooked both by the patient and physician, until effusion has actually taken place from the inflamed vessels, when we can do little more than diminish the sufferings of the patient, which in that state are very acute. It is certain that Hydrocephalus is a much more frequent complaint, since the more general use of mercury, particularly as prescribed in the diseases of children. The observations of Blackall, Beddingfield, Wright, and Pemberton, on the increase of excitement produced by mercury, and the aggravation of inflammatory diseases by the use of that metal, are an additional evidence of its injurious effects in Dropsy of the Brain. In several instances, the writer has seen Hydrocephalus as the result of the infantile remittent fever, which, in its commencement, was overlooked by the practitioner, and its termination in Hydrocephalus has been made the cloak for his ignorance. The frequent observance of this fact has led us to divide Hydrocephalus into two species; idiopathic, traceable to predisposition from hereditary conformation of the brain; and symptomatic, the effect of injuries of the head, febrile and other diseases, more espe-

Sect. IX. *Spasmi Epilepsia. Epilepsy.*

After the two first orders of the Neuroses, including the diseases that are characterized respectively by an increase, and by a diminution of the nervous power, we come to the third order, where it is exercised in an irregular manner; to these we give the name of Spasmi. We derive the genera of the Spasmi from the relation which the part affected bears to the exercise of volition, into diseases of the voluntary muscles, the involuntary muscles, and those which possess a middle rank between the two. One of the most important of the species belonging to the first genus is Epilepsy. This disease may be shortly defined a sudden accession of violent convulsions of the whole body, with a loss of sensation and voluntary motion. Each attack continues for comparatively a short period only, when the patient recovers his usual state of body and mind, and experiences a degree of stupor and drowsiness, but without any recollection of what has passed. Although, however, the effect of a single fit is not productive of any visible change upon the animal economy, yet, when the disease recurs frequently, and the attacks are violent, the functions that depend upon the nervous system gradually become weakened, and ultimately much deranged, so as to bring on imbecility of the mental faculties, and an imperfect power over the voluntary muscles. It has been usual to divide Epilepsy into idiopathic and sympathetic; the latter being supposed to depend upon some obvious exciting cause; but we do not apprehend that there is any real foundation for this division; it in fact amounts to no more than that in some cases we are able to detect the exciting cause, while in others we are ignorant of it. The exciting causes appear to be very various, originating from a great number of different circumstances, that bear different relations to each other, and all produce nearly the same symptoms. Those that generally fall under our observations are, 1st, Injury and malconformation of the skull, or the parts included in it; 2d, Certain states of the alimentary canal, particularly worms, or that morbid condition of their contents which is supposed to be favourable to the production of these parasitical animals; 3d, The peculiar irritation caused by teething; 4th, Violent mental emotions, especially surprise and terror; 5th, Repeated intoxication; and, lastly, an hereditary tendency in the constitution, which we are not able to describe or define, although we can have little doubt of its existence. The invasion of Epilepsy is sometimes so sudden, that the patient has not the least warning of its approach, but falls down at once in a state of complete insensibility; at other times there is a feeling of oppression in the head, with vertigo, dimness of sight, and confusion of thought, and occasionally there is a peculiar sensation of cold, which has been named the aura epileptica, passing up from some part of the body to the head, when the complete paroxysm comes on.

As the disease seems to originate from such a variety of causes, so its prognosis is extremely uncertain, and its cure has been attempted by a great variety of means. When the exciting cause is clearly ascertained, we, of course, direct our whole attention to the removal of it; and the success of our attempts in this way must entirely depend upon the degree in which this can be accomplished. When the cause is not obvious, we have but little to guide us in our operations, except a reference to the general state of the functions, and some analogies which are too often very obscure and uncertain. The state of the bowels is one of the first things to be attended to; and, in children, we are often able to remove very formidable attacks of the disease, by completely evacuating the alimentary canal. It is generally the custom to make calomel one of the principal ingredients in the purgatives that are administered in Epilepsy, and it is probably used with more advantage when united to jalap, scammony, colocynth, or some of the drastic medicines of this description. When the digestive organs seem to suffer from acidity and flatulence, or from any other particular symptom, we are to endeavour to remove them by the appropriate remedies; and when there is a general weakness of the digestive organs, we employ, according to circumstances, stimulants, stomachics, and tonics. It has been proposed, in those cases where the fit is preceded by the aura, to cut off the communication between the part whence the peculiar sensation proceeds and the brain, by compressing the nerve, or even dividing it; but it is doubtful how far this practice has been attended with success, or how far we ought to expect any benefit to be derived from it. When there is no obvious exciting cause, and when the different organic functions do not exhibit any evident irregularity, we can have but a faint prospect of removing the disease; and our practice must, for the most part, proceed entirely upon empirical principles. In this, as in all other similar cases, we find, that in proportion to the obscurity of the complaint, and the real difficulty which there is in relieving it, so is the number of infallible remedies that are held out to the hopes and fears of the unfortunate sufferers. The remedies that have been proposed for Epilepsy, under this form of the disease, may be divided into three classes; those that are called antispasmodics, generally possessing some property that powerfully affects the external senses; tonics, and a miscellaneous description of remedies, which can only be referred to their power of acting upon the imagination. Some of the principal antispasmodics are ether, valerian, castor, and musk, to which it has been the custom to add opium, and various other sedatives In certain cases of convulsions, we conceive it not impossible that benefit may have been derived from these substances; but we have no conception that they can have any great power over proper Epilepsy. The second division of remedies, the tonics, although of very problematical operation, possess more claim upon attention. Of these the most powerful are certain metallic salts, as the nitrate of silver, cuprum ammoniatum, the oxide of zinc, and various salts of iron and arsenic. In what manner these

---

cially such as occur in early life, when the undue determination of blood to the brain is an ordinary occurrence. When Hydrocephalus can be detected in its forming stage, much may be done, not by the usual medicine, mercury, but by the lancet, cupping, a blister covering the scalp, by active saline cathartics, and by other means of depleting the system and restoring the natural excretions. The practice of administering mercury in Dropsy of the Brain cannot be too severely reprobated. It has again and again been the cause of the disease, when administered for worms, and in other complaints where the patient did not previously manifest the least tendency to an affection of the brain.

Hosack.

substances act, and for what particular varieties of the disease, or states of the system, they are each of them more particularly serviceable, are points on which we have little certain knowledge. Vegetable tonics are among the remedies usually prescribed for Epilepsy; of these cinchona may be supposed to supersede all the rest, although, by way of giving variety to our prescriptions, we may substitute other articles of the same description, or may occasionally give them in combination. We have mentioned worms among the exciting causes of Epilepsy, and this appears to be the case more particularly with the tape-worm. As the oil of turpentine seems to act very powerfully upon these animals, we may be fairly allowed to try the effect of turpentine in all cases of Epilepsy that have baffled our other means, even when we have no evidence of the existence of the tænia, more especially as the indications of its presence in the intestines are not always very obvious.

Nearly allied to Epilepsy, and perhaps differing from it chiefly in degree, are the convulsions with which children are so frequently attacked, more especially about the period of dentition. These affections are generally removed as the exciting cause ceases to operate, and are not productive of any permanent injury to the constitution. It is, however, necessary to use the appropriate means for facilitating the passage of the teeth through the membrane that covers them; while, at the same time, it will be desirable to evacuate the bowels completely, and to be extremely guarded with respect to the diet. The paroxysm is supposed to be shortened or relieved by immersing the patient in the warm bath; and it is a remedy which may be always employed with safety, if not with advantage.

Sect. X. *Hysteria. Hysteric Disease.*

Hysteria is a disease of so multifarious an aspect, which exists under such a variety of forms, differs so much in its violence at different times, and is so peculiar in its nature, and in its effects upon the animal economy, that we feel some difficulty in giving a concise and summary account of it.

It usually occurs in fits or paroxysms, which considerably resemble those of Epilepsy, except that they are less violent, and that the consciousness is not altogether lost; but there is the same convulsive exertion of the limbs, and the sensations and mental faculties, although not entirely suspended, are much disordered and perverted. There is likewise in Hysteria a symptom which may be conceived to bear some analogy to the aura epileptica, which has obtained the name of the globus hystericus. It commences with a peculiar feeling of pain and distention in some part of the abdomen, which gradually rises up the course of the intestinal canal, until it reaches the stomach, and, finally, the upper part of the throat, where it remains stationary, and seems to threaten immediate suffocation. The convulsive affections now come on, and are attended with faintness and partial insensibility, while the patient laughs and cries alternately, exhibiting almost an appearance of delirium or fatuity, until the paroxysm is terminated by an eructation of flatus, to which succeeds a copious discharge of pale urine, and sometimes a degree of stupor and drowsiness.

The nature of the convulsions, as well as of the other symptoms, varies in all possible ways. Sometimes the limbs are rigidly fixed in one position; at other times they are violently agitated: occasionally there is a general stupor approaching to coma; at other times pains are felt, which are so violent as to cause the patient to utter the most horrid screams.

There is something very mysterious about the exciting causes of Hysteria. It appears, in many cases, to be merely a mental affection, induced by violent passions or strong emotions; and so much is this the case, that the patient is certainly able, by voluntary exertion, to prevent the accession of the disease, which, if it had been suffered to proceed in its usual course, would have assumed the formidable appearance that has been described above. The symptoms are frequently induced by a kind of imitation, where the sight of a patient labouring under the disease will bring a similar disease on the by-standers. These facts have led some persons, both professional and unprofessional, to consider Hysteria as always a fictitious complaint; one entirely under the control of the will; which, like the expression of anger, may be always restrained, being assumed for the purpose of exciting sympathy, or other similar motive. To a certain extent this may be true; but we apprehend that no one who has frequently witnessed the disease in its aggravated form, can suppose that it is always so. Indeed, we cannot conceive how any voluntary effort could produce the effects upon the various organic functions, that are so frequently observed in this disease, or that any thing, except a highly morbid condition of the animal economy, could enable the patient to perform the convulsive muscular exertions, which far exceed what is ever observed in the same individual at other times. It is well known that Hysteria is almost entirely confined to females, and, among these, it is generally met with in those of feeble muscular powers, but of great nervous sensibility. Some instances occasionally occur in the male sex, which we think are entitled to be classed with Hysteria, whose state of body and mind are most similar to the female constitution. We have already mentioned the resemblance which Hysteria bears to Epilepsy; and we conceive that it is often extremely difficult to distinguish between them, where the one disease appears in its mildest, and the other in its most acute form. The *globus* is not always present in Hysteria; and there are certain cases which seem entitled to the appellation of Epilepsy, yet where the insensibility is not complete, and where the state of the feelings and of the nervous functions very much resemble what has been described as characterizing Hysteria; and, besides this, the diseases are sometimes evidently convertible into each other, what begins under the form of Hysteria finally terminating in Epilepsy.

Hysteria, when it appears in its unmixed form, and is not the forerunner of Epilepsy, or symptomatic of any other disease, is seldom attended with danger, although it may be difficult to remove. Our indications are to prevent or cut short the paroxysm, and to obviate its return. The first is accomplished by any sudden impression upon the mind or the organs of sense. The general directions for this purpose it is almost impossible to lay down, as so much depends upon the peculiar circumstances of the case, both with respect to the bodily and mental constitution of the patient. A fit has been prevented by suddenly dashing cold water over the patient, by antispasmodics, carminatives, or stimulants, and by various means which only operate through the medium of the imagination. In order to prevent the return of the fit, we endeavour to restore the due balance between the powers of the system, by increasing strength while we diminish action. This is accomplished principally by tonics of various kinds, vegetable and metallic, of which, perhaps, the most efficacious is cinchona, combined with some preparation of iron. Among the auxiliary means, we may mention bodily exercise, the cold bath, abstinence in diet, early rising, and such other means as are generally allowed to invigorate the system, while, during the whole course of the disease, we are to be especially careful to preserve a very open state of the bowels.

Sect. XI. *Chorea. St. Vitus's Dance.*

This is a peculiar kind of convulsion, which principally affects the extremities, and generally the arm and leg of one side more than the other. It consists in a loss of voluntary power over the parts, so that the patient is unable to move them in the required direction, while they are subject to a variety of spontaneous motions, which he has it not in his power to restrain. Other parts of the body, especially the face, are subject to involuntary twitchings; and, when the disease is violent and has been of long standing, the speech becomes affected, and at length a degree of fatuity supervenes.

Chorea makes its first appearance almost exclusively in young persons, for three or four years previously to the period of puberty; but if it be not removed by proper remedies, it will continue, in a certain degree, for a long period, or even during the remainder of life. The patients are generally of a delicate habit of body, and such as have not enjoyed a sufficiency of nourishment, fresh air, or bodily exercise. It occasionally occurs in paroxysms, or, at least, is more violent at some times than at others; but generally its progress is gradual, first exhibiting itself in certain gestures or motions of the limbs, which seem rather objects of ridicule than of medical treatment. Sometimes the first symptom that is noticed is a dragging of the leg in walking, similar to what we obseve in slight paralysis. Along with the more appropriate symptoms we generally find, that the digestive organs are deranged, and especially that the bowels are torpid. The disease, in some cases, appears to be sympathetic of a local irritation, such as that from teeth or from worms; but, generally, we do not observe any local exciting cause to which it can be referred. It is said to be disposed to disappear spontaneously at the age of puberty, but we doubt the correctness of this observation.

The cure of Chorea has been attempted by various means that are very opposite to each other. By some authors depletion is recommended, while, by others, tonics and stimulants are prescribed; and in each case the remedies are directed generally with little regard to the nature of the individual cases, or the difference which may exist between them. This apparent inconsistency, perhaps, depends partly upon the nature of the complaint, which, like some others of the Neuroses, may arise from causes that are almost diametrically opposite to each other, and yet may exhibit nearly the same symptoms. The plan of treatment which we shall recommend is, that the state of the bowels be always the first object of attention; that brisk cathartics be administered, consisting of calomel combined with a drastic purgative, until the evacuations are of the natural quantity and quality. If the appetite be defective, we should then administer stomachics; and if the system exhibit marks of general weakness, we may employ tonics and stimulants. We believe that less advantage will be obtained from the use of opium and other sedatives, than the nature and the symptoms of the disease might lead us to expect; nor do we apprehend that much will be gained by the tribe of antispasmodics. The application of blisters to the origin of the nerves which supply the affected part, especially to the different regions of the spine, has been found a useful practice; mercury given so as to effect the system, has been strongly recommended by some writers, and likewise electricity; but we do not feel much confidence in either of these remedies. We need scarcely remark, that it is extremely important in all cases of Chorea to examine the state of the teeth, and to remove every probable cause of irritation which may seem to be derived from this source.

Sect. XII. *Tetanus.*

By Tetanus, in its most extensive sense, we mean a rigid contraction of any muscle or set of muscles; but it is usually applied to a general condition of the system, where all the muscles of the body, and especially those of the trunk, neck, and jaws, are in a permanently contracted state, so as to render the patient almost incapable of motion, speech, and deglutition, while the most acute pain is experienced in all the affected parts, and particularly about the pit of the stomach and over the abdomen. The disease is sometimes principally confined to the jaws and the neighbouring parts, when it is styled Trismus or locked jaw. It usually commences with a degree of stiffness in the back of the neck, with some difficulty in opening the mouth; to this succeeds the rigidity of the muscles of the trunk, where it is often so violent as to bend the body into the form of an arch, and it finally extends to the extremities. The disease is aggravated by paroxysms, which are generally, but not always brought on by some voluntary exertion, as by changing the posture, or by swallowing, when the contractions become much more forcible, and the pains more acute, until the patient is carried off in one of these accessions, exhausted as it were by his excessive exertions, and worn out by the violence of his sufferings. The exciting causes of the disease are of two kinds; the most frequent in this climate is a certain species of mechanical injury, not productive of much pain, but exciting a specific irritation, which, from some unknown cause, affects the nerves so as to induce the disease. Wounds of a nerve are perhaps the most frequent cause, but laceration of a tendon is also said to excite it; and it is often observed to follow gunshot wounds or surgical operations, in which large bones have been divided; in these cases it is generally supposed that a loose splinter of bone has been left in the wound, that a nerve has been torn, or perhaps included in a ligature. The other class of the exciting causes of Tetanus is even more obscure; it occurs principally in hot climates, and generally originates from those circumstances that are supposed suddenly to check the cutaneous perspiration, where the body is exposed to damp and cold after great heat; of these one of the most frequent occasional causes is sleeping on the moist ground, after violent exercise under a tropical sun. It does not appear that the symptoms of the disease in these two varieties are materially different, although arising from such different causes; but those of the latter kind, which are termed idiopathic, are, for the most part, less violent than such as arise from wounds or other mechanical injuries. Although fever is not an essential symptom of the disease, yet, after it has subsisted for some time, the pulse becomes accelerated and the temperature increased; and it has been supposed that the best means which we possess of forming a prognosis is derived from the state of the pulse, especially with respect to its velocity.

In attempting the cure of Tetanus, the first object is to remove the source of irritation, if it depends upon any obvious mechanical cause; if it proceeds from a wound of any kind, it has been recommended to divide the nerve which passes from the wounded part to the brain; but this practice has not been attended with the expected relief, nor has even amputation of the limb been successful, when the disease has once taken possession of the constitution. Applying caustics, or heating stimulants, as the oil of turpentine, to the wound, so as to produce a copious suppuration in the part, has been thought to afford a probable means of relief, upon the principle that where Tetanus has followed from a mechanical injury, the discharges have assumed an unhealthy aspect. It is, however, extremely doubtful whether any advantage has been derived from these practices, and at all events our main reliance is to be placed upon internal remedies, of which the most important is opium. When the symptoms of the disease unequivocally manifest themselves, we must immediately have recourse to this medicine in frequently repeated doses; the extent of the dose must depend upon the effect which it produces on the system; but the quantity which has been taken in this disease is very large, and much more than could have been borne in the ordinary condition of the functions. Many substances have been united with opium, upon the idea of increasing its efficacy, but it may be questioned whether they are of any essential benefit; perhaps indeed in those cases where there is much fever, a combination of opium and ipecacuanha may be preferable to opium alone. Some cases are upon record where idiopathic Tetanus has been relieved by dashing cold water over the patient, or by immersing him in the cold bath, but this has probably been in the slighter cases only, and in Tetanus from wounds has been found completely useless, perhaps even injurious; for in such cases the sensations of the patient rather indicate the application of warmth than of cold to the surface. Besides the internal exhibition of opium, it has been found to produce its appropriate action on the system, by being rubbed on the skin in the form of ointment; when the process of friction does not add to the sufferings of the patient, this will at all times be found a useful adjunct to the internal exhibition of the remedy; and where the deglutition is very much impeded, we are under the necessity of entirely depending upon it. Mercury, which in modern times has been regarded by some authors as a universal panacea for all complaints, has been employed in Tetanus, and, as we are informed, with the usual success; but it has not produced the same good effect in other hands. Wine or ardent spirits, taken in large quantities, has been recommended in Tetanus, and some cases are upon record where this plan has appeared to be successful; but upon the whole we think it is less effective than opium, and we percieve no motive for preferring it. Purgatives in this, as in all the Neuroses, are valuable adjuncts to our other remedies, but in Tetanus we are not to depend upon them as affording a radical means of cure.

Sect. XIII. *Colica. Colic.*

Perhaps the only idiopathic disease which can be considered as belonging to the next genus of the Spasmi, those which consist in an irregular action of the involuntary muscles, is Colica. Colic consists in pain of the bowels, especially characterized by a twisting sensation in the umbilical region, accompanied with spasmodic contraction of the abdominal muscles, and obstinate costiveness. There are many varieties of Colic, which are clearly referable to different exciting causes, but which nearly resemble each other in their symptoms: the peculiar state of the digestive organs, and of the biliary secretion; various articles of food, or merely an excessive quantity taken into the stomach; retention of the fæces; the application of cold and moisture to the feet; perhaps worms; and certain metallic poisons, particularly lead. It has been ascribed to a metastasis of gout from the extremities, and it has been supposed that the intestines were subject to Rheumatism; but whatever be the origin of the disease, it is probable that its proximate cause is always the same, an irregular contraction of the muscular fibres of some portion of the intestinal canal. When this state proceeds to a very violent degree, the peristaltic motion of the bowels is entirely inverted, and the fæces are even discharged by vomiting; occasionally the bowels have their action so much deranged, that one portion which is much contracted is forced into another which is less so, forming what has been called an intus-susception: the disease in this aggravated form has been termed Ileus, or the Iliac passion. There is no fever necessarily connected with Colic, and by this circumstance it may be distinguished from Enteritis; another diagnosis is, that in Enteritis the pain of the abdomen is increased by pressure, whereas in Colic it is perhaps rather relieved by this means; but although the diseases are essentially different from each other, yet Colic, if not speedily relieved, is liable to produce inflammation. On this account, when it is violent, we are frequently obliged to commence with blood-letting, which both obviates the subsequent tendency to the inflammatory state, and renders the exhibition of purgatives more effectual. The great object, however, is to procure the discharge from the bowels; but when the vomiting is severe, this is a point which it is often difficult to accomplish. For the most part it is dangerous to promote the tendency to vomiting, lest we should produce an inversion of the peristaltic motion of the intestines, yet sometimes the stomach is relieved by the free evacuation of its contents, and occasionally a single dose of opium is useful under these circumstances. We are, however, to place our main dependence upon purgatives, administered in frequently repeated doses, of such strength as the stomach will bear, and in the form which is least obnoxious by their bulk or their sensible qualities. The operation of purgatives is much promoted by injections, which should be as capacious as the parts will receive; and we may render them more active by mixing some cathartic ingredient with them.

The choice of the purgative depends upon a variety of circumstances, connected with the habits and constitution of the patient, for which it is not easy to lay down any general rules. Some practitioners place great confidence in calomel, either alone or combined with some drastic, as colocynth or scammony; where the stomach will retain it, and the disease is not too violent, oleum ricini is a safe and effectual remedy, and in most cases the neutral salts, especially the sulphate of magnesia, will be found useful adjuncts to the more powerful remedies. The patient is often much distressed with flatulence, for which he may obtain temporary relief by carminatives and stimulants; the latter, however, must always be given in small doses. When the bowels have been fully evacuated, the pain is generally relieved or much mitigated; but if this be not then the case, we may safely administer opium. Should there be much soreness of the abdomen, which is increased by pressure, indicating a tendency to inflammation of the peritonæum or the neighbouring parts, leeches or blisters will be proper; and in most cases we shall find relief from hot fomentations, or the warm bath. Persons who have suffered from Colic should be extremely cautious with respect to their diet, and should carefully guard against external cold, as it is found that a severe fit of the complaint always lays the foundation for subsequent returns of it, which may terminate either in acute inflammation, or may lead to some organic disease of the part, less rapid in its progress, but equally fatal in its ultimate result.

We have placed in this part of our system the disease of Tympanitis, an affection which is characterized by an enlargement of the abdomen, caused by a collection of air, either contained within the intestines, or diffused through the cavity of the peritonæum. Although it is generally described as a primary affection, we think there is much obscurity attached to it, and we are even disposed to doubt of its existence as more than a mere symptom of Dyspepsia, at least in that variety where the air is retained within the bowels. With respect to the other variety, it must necessarily be the result of a structural derangement of the part, as consequent upon some other disease, and is obviously incompatible with the existence of the patient for any great length of time. Many of the cases which have been described as Tympany we should be disposed to refer to Dropsy, and others to enlargement of the mesenteric glands, in both cases accompanied by flatulence, arising from the weakened state of the digestive organs, which usually attends this complaint.

Sect. XIV. *Pertussis. Hooping-cough.*

The third genus of the Spasmi contains the diseases that originate from irregular contractions of the semi-voluntary muscles, consisting almost exclusively of certain affections of the thorax, or the parts immediately connected with it. The diseases which may be regarded as primary, or of sufficient importance to claim our attention, are Tussis, Pertussis, Dyspnœa, Asthma, and Angina pectoris. Although we think that cases of cough occasionally occur, which cannot be referred to any more general affection, and which must be regarded as merely nervous, yet, as the disease is generally symptomatic, and when it is not so, may depend upon a variety of causes, which must necessarily render it almost impossible to lay down any general principles for its cure, we shall not attempt to give any farther account of it in this place, but shall proceed to the consideration of the next species, Pertussis. This is a peculiar kind of cough, which is characterized by several symptoms that point it out as a disease of a specific nature, a circumstance which is decidedly proved by the fact of its occurring only once during the life of each individual, and by its being propagated by contagion. It comes on in violent paroxysms of repeated short expirations, which are succeeded by a quick, deep inspiration, attended with a peculiar sound, that has obtained the name of hoop, or whoop, from which one of its popular names, that of Hooping-cough, is derived. The paroxysm is often terminated by vomiting, and induces a state of great debility and exhaustion, which, however, is so transient, that after the patient has been struggling for breath, and apparently almost expiring, in a few moments his functions resume their natural state, and he exhibits scarcely any traces of disease. As the complaint is contagious, and occurs once only during life, it necessarily happens that children are the most frequent subjects of it; but when it has not been gone through during childhood, every age seems to be equally liable to its attacks. There are few circumstances in pathology which are more difficult to explain than the manner in which a disease like Hooping-cough can prove contagious, which is not necessarily of a febrile nature, where there appears to be no matter generated which can be the medium of infection, and where there is nothing of the putrid or malignant nature, which is supposed to indicate a tendency to decomposition in the constituents of the body. As a point of practical importance, it has been questioned whether the contagion can be conveyed by a third person. We are not in possession of any facts which can enable us to decide positively on this subject, but we should suppose that this could not be the case, but that the breath of the patient must be actually inhaled in order to produce the disease. But, whatever conclusion we may form upon this point, we have sufficient evidence from our daily experience, that contagion is its most usual, if not its only cause. When a patient is under the influence of the complaint, the individual paroxysms are generally brought on by some obvious cause, as by muscular exertion, by taking food, or even by sudden mental emotions. At its commencement, the symptoms are scarcely to be distinguished from those of a common catarrhal cough, and three or four weeks often elapse before the characteristic marks of Pertussis make their appearance. The cough gradually becomes more severe, the expirations succeed each other more rapidly, and are followed by the sonorous inspiration, vomiting then comes on, and the patient falls into a febrile state, which seems to aggravate all the other symptoms. During the violent paroxysm of coughing, the passage of the blood through the lungs is so much impeded as to produce a deep suffusion of the face; and it frequently happens that some of the small arteries are ruptured, and that blood is discharged, mixed with the matter expectorated, or bursts out through the thin cuticle of the nose and mouth. When the disease has acquired its greatest degree of violence, it remains for some time stationary, and then declines. The period which it occupies in the whole process is very uncertain, and it is sometimes protracted for many months. Whenever it exists in its aggravated form it is accompanied with fever, and, although not necessarily of an inflammatory tendency, it often produces inflammation of the chest, and in this way proves fatal. In persons who are disposed by hereditary constitution to Phthisis, this complaint is frequently brought on by the Hooping-cough, and occasionally it seems to lay the foundation for a state of general marasmus or tabes, which ultimately proves fatal without the lungs being the actual seat of disease.

The cure of Pertussis is often tedious and embarrassing, and we have scarcely any general principles by which to direct us in our course. General bleeding is sometimes necessary at the commencement, and leeches may frequently be indicated by the pain or soreness of the chest; but it is not a disease in which copious depletion is necessary, or in which it appears to be attended with benefit. As the paroxysm is usually terminated by expectoration, so it has been the great object of the practitioner to administer medicines which may promote this process. Unfortunately, however, they are of very uncertain effect, and very dubious operation; and it not unfrequenly happens that greater injury is experienced by their heating or stimulating quality, than is compensated by any benefit to be derived from the discharge of mucus which they produce. Perhaps the most unexceptionable of this class are those that act as emetics; and, upon the whole, we think that the most effective treatment of Pertussis consists in giving ipecacuanha, so as to produce gentle vomiting once or twice daily. Antimony we think less proper, on account of its debilitating operation, an objectionable circumstance in a disease of such long continuance, and where the patients are often young and delicate. Diuretics have been prescribed in Hooping-cough; but we doubt whether they are of any use, while they are liable to the same objection with the expectorants. Next to emetics, perhaps the most generally useful remedies are blisters, which may be small, but frequently repeated. The disease is apt to degenerate into a chronic state, and, when all the inflammatory symptoms are gone, but the cough still remains violent, opium becomes admissible, and is often found very effectual; its good effects are increased by being combined with ipecacuanha. We have not much confidence in the tribe of antispasmodics which have been recommended in Hooping-cough. There is, however, one remedy, which, in the latter stage, is universally admitted to be very useful, a change of air; and it is remarkable, that it appears to be merely the circumstance of change, and not any quality in the air itself, as the same benefit is obtained, by taking the patient from the pure air of the country to the confined atmosphere of a crowded city.

Sect. XV. *Asthma.*

We not unfrequently meet with symptoms of simple Dyspnœa, which we find it difficult to refer to any other primary affection, yet it is so generally sympathetic, and its treatment depends so much upon the particular circumstances of the individual case, that we shall dismiss the farther consideration of it, and proceed to Asthma. Asthma is characterized by difficult and painful respiration, in which the breath is drawn at short intervals, and with what is termed a wheezing sound, attended with pain, and a sense of constriction in the chest, and a degree of cough. It occurs in paroxysms, which usually come on about midnight. It is frequently attended with a copious expectoration of mucus; but at times this discharge is not present; and accordingly the disease has been divided into the varieties of moist and dry. When the fit comes on in the night, the patient is affected for some hours before the accession with langour and drowsiness, and a degree of tightness in the chest, with some cough. These symptoms gradually increase until the paroxysm arrives at its greatest degree of violence, when, in three or four hours, it subsides spontaneously, leaving behind great debility and heaviness. It not unusually happens, that the same train of symptoms occur for several successive nights, when the disease becomes less violent, and for a time totally disappears. Generally, the patient is able to trace these accessions to some obvious exciting cause. Certain states of the atmosphere, as the air of large cities, fogs, or exhalations from damp ground, indigestion, or repletion of the stomach, and violent exercise, are the circumstances which we observe to operate the most powerfully. When once the disease has invaded the constitution, and gone through a complete set of paroxysms, we find that it is much more easily excited than at first; and at length it occurs when we are unable to assign any probable reason for it. The proximate cause of Asthma is obscure. The morbid contraction of the muscular fibres of the bronchiæ, which has been usually employed to account for it, we conceive to be a point of doubtful existence, and scarcely adequate to the effect. There are, however, many circumstances connected with the disease, which lead to the supposition that it is a primary affection of the nervous system. We not unfrequently observe individuals who pass a long life under the influence of Asthma, and apparently do not experience any considerable evil, except the pain and inconvenience arising from the actual presence of the disease; but there are many cases in which it terminates in Phthisis, Hydrothorax, chronic inflammation of the chest, enlargement of the heart, Aneurism, &c. by inducing a state of gradual decline, in which all the functions lose their due action, and ultimately proves fatal.

The obvious indications of cure in Asthma are, to moderate the violence of the paroxysm, and to prevent its recurrence, both of which we unfortunately find it very difficult to accomplish. Although the violence and frequency of the disease have rendered it an object of great attention to all practitioners, so that every one must have had much experience of the effect of remedies upon it, yet still we feel considerable uncertainty respecting their operation, or the degree of benefit which is to be expected from them. Depletion does not, upon the whole, seem to be useful; and although the sense of fulness about the chest, and the febrile state of the system, during the paroxysm, might seem to indicate bleeding, yet we believe it has not been productive of the expected relief. Nor is the good effect of purgatives so evident as in many of the Neuroses; and we may make the same remark with respect to blisters, which, in affections of the chest, are usually resorted to with much advantage. The fit frequently terminates in expectoration; yet it would not appear that any decided advantage is obtained by the administration of what are termed expectorants, and even emetics are said to have failed in shortening the paroxysm, while the efforts to evacuate the contents of the stomach have materially added to the distress of the patient. Very favourable reports have been made of some of the sedatives or narcotics, especially tobacco and stramonium; but it does not appear that they are equally successful in all cases, and where they have proved efficacious when first employed, they have afterwards appeared to lose their power; the same remarks may be made respecting opium, which, in moderate doses, has occasionally proved useful, but perhaps has more frequently failed. The inhalation of the steams of hot water is a palliative, which may be safely employed; and as the patient is usually affected with flatulence and eructations, we may obtain some relief from magnesia and the carbonated alkalies. Nor are the means which we possess for preventing the recurrence of the fit much more certain than those for shortening its duration. When Asthma is connected with any constitutional malady, it will be proper to endeavour to remove this latter, or if possible to obviate its exciting cause; and we must carefully watch the state of all the functions, more particularly of the stomach and bowels, and endeavour to restore their healthy action when deranged, but beyond this we fear that our efforts will be nearly unavailing. Like other nervous diseases, Asthma is supposed to degenerate into that chronic state, in which the paroxysms occur, although the exciting cause is no longer supposed to exist, as if by the force of habit. It may indeed be doubted how far this idea is well founded, but we certainly observe instances where the complaint appears to be relieved by a change of situation, or a complete alteration in the mode of life and occupations of the patient.

Sect. XVI. *Angina pectoris.*

This disease is characterized by sudden attacks of acute pain in the lower part of the chest, which shoots up the shoulder and extends down the arm of the left side: they are attended with laborious respiration and an apprehension of immediate suffocation, while there is frequently an irregular action of the sanguiferous system, or even a temporary suspension of the motion of the heart. The paroxysms are of short duration, and come on at uncertain intervals, while, at other times, the patient is nearly in his ordinary state of health, until the disease, by frequent repetition, gradually undermines the constitution, and the attacks become more and more violent, until at length one of them proves fatal. Their accession may generally be traced to some obvious exciting cause, of which the most frequent is walking briskly up a steep ascent, and this is especially the case, when the stomach is in a state of repletion; mental emotions are also among the exciting causes of the paroxysms; and when the disease exists in its violent form, it may be induced by almost any muscular exertion, however slight, or even without any obvious cause. It is not a little remarkable, that until about the middle of the last century, this affection, although so severe and well marked in its symptoms, and not of very rare occurrence, should have passed unnoticed as a distinct disease. Latterly, however, its phenomena have been accurately described, and its nature carefully examined; and we learn, as the result of this examination, that it is generally connected with an ossification of some of the valves or orifices of the heart. Although this change of structure has not been detected in every instance, yet we may conceive of other circumstances producing a similar effect upon the transmission of the blood through the heart, and may therefore conclude that its proximate cause is always to be referred to some circumstance connected with the mechanism of the circulation. With respect to the cure of the disease, our hopes of relief must depend very much upon the period when it comes under our care; in the latter stages, where ossification has actually taken place, we can do little more than use all our endeavours to obviate the exciting causes; but in the earlier stages, when there is no morbid change of structure, very decided benefit has been obtained by large caustic issues. Our attention is forcibly directed to the situation of the patient during the paroxysm, which is not only attended with exquisite suffering, but is sometimes immediately fatal. Yet it is doubtful whether any thing, except rest in the horizontal posture, will be of service in shortening the fit, or mitigating its violence. It is of great importance to preserve the stomach and bowels in a healthy condition, by a strict attention to diet and purgatives, and we must avoid all undue action of either the bodily or the mental powers. It does not appear that opium, or any of the antispasmodics, afford relief in this complaint, and we conceive that the employment of stimulants or excitants might be positively injurious.*

CHAP. III.

Vesaniæ. Diseases of the Mental Faculties.

We have arranged the idiopathic affections of the mental faculties in a separate class, under the denomination of Vesaniæ; for although we may conceive, that they always depend upon some derangement of the brain, the instrument by which they are exercised, yet their phenomena are so peculiar, and the relation which exists between the corporeal and the intellectual part of

* The text seems most partial to the theory of Angina Pectoris, maintained by Dr. Parry; it is unquestionably the most popular one, though many circumstances might be mentioned, which strongly militate against it. The writer of this note is of opinion, that Angina Pectoris, for the most part, proceeds from an inordinate fulness of the vascular system, more especially from a disproportionate accumulation in the heart and larger vessels. The great accumulations of fat, the effusion of water in the thorax and pericardium, the distended state of the vessels, and even the earthy deposits occasionally met with in the valves and vessels of the heart, may be considered the effects of such plethora. This pathological view is strengthened by observing that the persons most liable to attacks of this disease, are those in advanced life, of corpulent and gouty habits, with short necks The attacks of this disorder occur most commonly in the winter and spring; the patient, moreover, often suffers from spontaneous discharges of blood in different parts of the body, anxious and oppressive breathing, numbness of the extremities, giddiness, and other symptoms indicative of an overloaded state of the blood-vessels. Dissections lead to the same conclusion. The mode of treatment is pointed out in the circumstances above mentioned; copious depletion by the lancet, and active cathartics must be had recourse to; issues have also been followed by beneficial effects; and for the removal of the spasm, palpitation of the heart, and coldness of the extremities, æther, volatile alkali, and other diffusible stimuli, are to be exhibited. Opiates, after blood-letting, are often used with advantage. Warm bathing and friction of the extremities, are also useful. A due regard to diet and regimen, are of great consequence in preventing the return of the disease.

Hosack.

our frame is so obscure, as to be altogether beyond our comprehension, at the same time that the two kinds of diseases require a totally different method of treatment. This part of medicine has unfortunately been much embarrassed, by the application of what has been termed metaphysical reasoning, but which has, in fact, consisted of the use of certain ill-defined and unmeaning phrases; the effect of which has often been, to produce the same confusion in the mind of the reader, which must have existed in that of the writer. Another, and perhaps a still greater source of difficulty, in every thing that respects the pathology of insanity, has arisen from an unreasonable prejudice that has attached to certain opinions respecting the nature of the intellectual faculties, in consequence of their being supposed to be adverse to religion and morals. Respecting the real merits of the doctrine of materialism, the one here alluded to, we do not pretend to decide; but we consider it a fair and legitimate object of philosophical inquiry, and it is one which is intimately connected with any hypothesis that we may form respecting the nature of the human powers, and their relation to the external world. It has not, however, any immediate or necessary connexion with pathology; for, whatever may be our opinion respecting the cause on which the faculties ultimately depend, we know that they are always exercised through the intervention of the brain; and with respect to the subject of insanity, it becomes an important practical question, whether the structural derangement of this organ corresponds, or is proportional to the mental disease. On this point, we are disposed to decide in the negative; for although we are informed, from high authority, that whenever the brain has been accurately examined in cases of insanity, some disease in its structure may be detected, we are of opinion, that it frequently bears no proportion to the violence of the complaint, while, on the contrary, we have equally numerous cases of great destruction, or disorganization of the brain, without a corresponding injury of the faculties.

Insanity has been divided into different genera and species; but we think it sufficient to consider it under two forms only—that where the faculties are prevented, and that where they are, in a greater or less degree, destroyed; the first constituting Mania, the latter Amentia. Although the phenomena of Mania are familiar to every one, both professional and unprofessional, yet there is perhaps no disease which it is so difficult to define, and the existence of which it is often so difficult to ascertain. The question of Insanity frequently comes to be discussed in courts of law, and we perpetually observe men of the most acute discernment and extensive information, differ in their opinion upon particular cases that are subjected to their judgment. This, in fact, depends upon a circumstance, which may appear sufficiently mortifying, that there are really no exact limits by which insanity can be separated from that state of mind which is deemed sufficiently sound to enable a person to transact the usual affairs of life. The most lamentable weakness of judgment, and the most singular perversion of the reasoning powers, unless exercised in a certain way, which is dangerous to the existence of the patient, or those about him, pass by as not differing from the condition of the rest of mankind, except in degree; and it is frequently from some accidental circumstance connected with it, that it acquires the name of disease, and subjects the patient to restraint and confinement. It is indeed usually more from the degree of the affection than any thing specific in its nature, that our judgment is ultimately formed, and rather by a detailed history of the circumstances of the case, and by comparing the present with the former state of the patient, than by any single diagnostic circumstance, that we finally decide.

There are several varieties of mental derangement which it is important to attend to; the first and most equivocal kind is that which consists in extreme caprice, or irritability of temper, and is the most difficult to discriminate from a sound state of the mind, as passing into it by shades that are absolutely insensible. Another variety is, where the disposition and habits undergo a complete change, which is independent of external circumstances, or of moral causes; a state that is often characterized by the mind becoming exclusively devoted to some one object, which is at one time of the most important, and at another of the most trifling nature, but still not decidedly beyond the limits of what may be considered as the result of rational deduction. From these we proceed to that variety of the disease where there is a complete perversion on one or two points; while on every other subject the mind retains its full powers; and from this we glide insensibly into that deplorable condition of the human nature, where the understanding is entirely deranged—where the individual is unconscious of the effect of his actions, and almost insensible to the impressions of surrounding objects upon the organs of sense.

Besides the difficulty which so frequently exists respecting the actual presence of the disease, other equally embarrassing points come under the cognizance of the physician. The first of these respects the question, whether the state of the patient requires his being removed from his friends, and whether the symptoms are such as to render him a proper inmate of a public asylum. As a general rule, we conceive it to be clearly established, that the patient is always best managed by those whose business it is to take care of the insane; and in a great majority of instances it seems that recovery is more promoted by the patient being removed from his accustomed abode, than by any plan which can be pursued, while he is surrounded by the scenes with which he had been previously familiar. The unpleasant association which must attach to a residence in a lunatic asylum is, no doubt, an objection to the removal, and formerly, while these institutions were regarded rather as places for coercion than for medical treatment, every one must have felt anxious to avoid the painful necessity of subjecting a friend or a relation to their cruel discipline. The enlightened spirit of the present age has, however, happily reformed the greatest part, if not the whole, of this system, and has thus not only rescued a large portion of our fellow-creatures from unmerited suffering, but has afforded them the prospect of a restoration to the blessings of health and the comforts of society.

In this brief sketch, we shall not enter into any detail respecting the means of curing insanity. One of our first objects must be to inquire into the exciting cause, and if possible to remove it; we are next to examine the condition of the system generally, and of the circulation in particular, whether there be any deviation from the healthy state, which we may have it in our power to relieve. Beyond this we have perhaps no general principles on which to proceed. The digestive organs are always to be carefully attended to, and in females we are minutely to watch the state of the uterine functions. The employment of the various means of depletion is to be regulated entirely by circumstances, and the same remark may be made as to the use of stimulants or sedatives; but, for the most part, the cure cannot be accomplished by the mere use of medicine, independent of general management or moral discipline. Every thing concurs to prove, that violence and harshness are as useless as they are inhuman; that constraint is only so far proper, as to prevent the patient from injuring himself, or those around him; that we must regard the insane as entitled to all the privileges of humanity; and that, when the reasoning powers are not too far perverted, they may, in a majority of cases, be restored, by treating the patient with a due mixture of gentleness and firmness, and by occupying him with such pursuits as may engage his ideas without harassing them. The cure of Amentia is more hopeless than that of Mania; it more frequently depends upon an obvious structural affection of the brain, and is more frequently either connate, or the effect of some irremediable injury. The treatment is the same for both the species, indeed there is no exact limit between them; so that, in the same patient, they often make their appearance at different periods of the complaint, or glide insensibly into each other. It may be observed, that the prognosis is more unfavourable when the affection is hereditary, or when it comes on without any obvious cause; while, on the contrary, the cases which consist of what is termed over-excitement, or violent delirium, are more easily relieved than such as seem to depend upon mere weakness, proceeding from a diminution rather than excess of nervous energy. With respect to the operation of particular remedies in insanity, we may remark, that bleeding is not to be employed, except there be some indication of its use from the state of the circulation. It does not appear to have any specific effect over the disease; and nothing can be more disgraceful to the profession, than the indiscriminate manner in which it was practised, until very lately, even in our first public establishments. The same observation may be made respecting all the other evacuations, which are only to be had recourse to when there is something in the state of the functions which seems particularly to call for their employment. Opium, camphor, digitalis, have each had their advocates, as well as the warm bath, the application of cold under various forms, and different kinds of mechanical exercises; but it may be doubted whether any very decided benefit ought to be expected from them, or at least more than what can be supposed to depend upon their effect in promoting the state of the general health. Many of the alleged cures of insanity have, no doubt, been accomplished through the medium of the imagination, where the complaint was only partial, so as to leave the patient in a situation to be conscious of what was passing around him; and, in some of the protracted cases, it must be attributed merely to the spontaneous effects of the system, inducing a salutary change in the functions, independently, or perhaps even in opposition to the means that were employed for the cure. See Insanity.

CHAP. IV.

Paratrepses.

Sect. I. *Dyspepsia. Indigestion.*

We now come to our fourth class of diseases, those which we have named Paratrepses, including the morbid affections that are concerned in the function of nutrition, of which the most important are the stomach, the intestinal canal, the liver, and the absorbent system. The first of the four orders into which we divide this class, consists of diseases of the stomach and its appendages, of which we begin by an account of Dyspepsia. Dyspepsia, or Indigestion, as it is popularly termed, is a complaint that is infinitely diversified in its symptoms, and depends upon a great variety of causes, some connected with the structure and composition of the parts, and others with their functions, independent of any visible alteration. It is a complaint which does not run through any regular course, or observe any uniform progress, but consists in a number of morbid actions, which succeed or accompany each other, as it appears, merely from incidental circumstances. Among the most common symptoms of Dyspepsia, we may enumerate the following: loss of appetite, or sometimes the contrary state of an acute feeling of hunger, while the stomach is incapable of digesting the food that has been received into it, nausea, vomiting, pain of the stomach, costiveness, or the opposite state of diarrhœa, morbid condition of the fæcal discharges, flatulence, heartburn, eructation, head-ach, and a furred appearance of the tongue; a circumstance which affords the practitioner one of the most certain indications of the state of the patient, and enables him to form his prognosis. The disease is not attended with fever, nor is the pulse necessarily affected, until it be so from the weakness which is induced when it is of long standing, and when the powers of the body begin to fail from the deficiency of nourishment. It is observed, that the mental faculties are much connected with, or influenced by, the condition of the stomach; so that the same individual, who possesses the most active and cheerful disposition while the digestive organs are free from oppression, after a full meal becomes languid, melancholic, and desponding. The exciting causes of Dyspepsia are as various as the aspects which the disease assumes. Every other disease, which in any way influences the state of the general health, may induce Dyspepsia; all violent mental emotions, especially those of a depressing kind; sedentary habits, or exercise carried to the length of exhaustion; and, what is the most frequent cause, and the one which produces the most urgent and distressing symptoms, a luxurious diet, or merely too great repletion; and especially the excessive use of fermented or spiritous liquors. The habitual employment of opium or tobacco seems to act very unfavourably upon the digestive organs; and, in short, whatever may be supposed either to diminish the vital powers, or to produce their irregular action, frequently manifests its injurious effects through the medium of the stomach. Another class of causes which impair the digestion, are those that consist in some structural disease of the various chylopoetic viscera, as chronic inflammation, contraction, or scirrhus of the stomach itself, which usually occurs about the pylorus; affections of the spleen and pancreas; and whatever impedes the due secretion of the bile, or its discharge into the alimentary canal.

The indications of cure to be observed in Dyspepsia are sufficiently obvious, but the accomplishment of them is often very difficult; and perhaps, in a majority of cases, we are rather to practise with a view to obviate particular symptoms, than in prosecution of any general principles. Our first object must be to ascertain, if possible, whether there be any structural disease of the stomach or the digestive organs, a circumstance which must materially influence our treatment, and still more our prognosis; for while we may hope to relieve the most obstinate dyspeptic symptoms, as long as the structure of the part is unimpaired, so our prospect of success must always be very small on the contrary supposition. In this latter case, the disease is to be regarded as entirely symptomatic, and, until the primary affection be removed, not only would most of the remedies that are proper for Dyspepsia be useless, but probably even injurious. When we have reason to suppose that the affection of the stomach is altogether independent of the structural disease, our first object is to inquire into the habits and modes of life of the patient, and especially into the nature of the diet; and, for the most part, we shall find that, by a proper regulation of these points, the most urgent symptoms may be relieved even more effectually than by the exhibition of the most powerful medicines. Yet painful and distressing as the complaint is, so much so as to destroy all the comforts of life, and even to render existence itself a burden, so inveterate are the habits of self-indulgence, and so unable is the patient to resist the calls of a pampered appetite, craving for its accustomed gratifications, that we too frequently find all our admonitions to be in vain, and our advice to be totally neglected. With respect to other remedies, the numbers that have been employed, and the various forms in which they have been administered, to accommodate the taste or the caprice of the patient, are almost infinite; but we may arrange them under the three heads of evacuants, stomachics, and tonics. It generally happens that the intestines are either torpid or in an unnatural state, and there is perhaps no instance of Dyspepsia, of all the numbers that fall under our care, in which we shall not find it highly beneficial to commence with active purgatives. They will be frequently found to supersede the whole tribe of carminatives, antispasmodics and antacids, which have been so liberally prescribed in this complaint, and will lay the best foundation for the subsequent use of stomachics and tonics. It would not be consistent with the nature of this treatise to enter into any account of the particular medicines, or combinations of them, which may be adapted to the various symptoms or conditions of the disease, but we generally think it desirable to employ them in a simple form and in small doses, and rather to rely upon a change in the external circumstances, which may be conceived likely to promote the general health, than upon the administration of any particular article of the materia medica. Country air and exercise, temperance in diet, avoiding the oppressive cares of business; and, we may add, as what is scarcely less necessary, the unreasonable pursuits of pleasure, are the grand remedies for Dyspepsia; and we conceive that no one who has given them a full trial, and has experienced the relief which is obtained from them, will be disposed to relapse into those luxurious habits, from which it is so difficult, in the first instance, to wean the patient.

Among the remedies which are of the most decided benefit in Dyspepsia, next to purgatives, and after they have performed their full effect, we may place the tribe of stomachics, consisting of the simple bitters, of which perhaps the most efficient are gentian and quassia; and, of those substances which seem to consist essentially of a bitter and an aromatic, of which we should select calomba and cusparia, as the most generally useful. Of the tonics, perhaps the most powerful in strengthening the digestive powers, is the union of one of the stomachics with iron: for simple pain of the stomach, the oxide of bismuth has been recommended upon high authority; but we apprehend that the complaint in which this medicine has been found so efficacious, is rather to be considered as a species of Autalgia, than the pain which is symptomatic of Dyspepsia. A very valuable medicine, and one which is applicable to every form of the disease, is the carbonate of potash; it appears not only to neutralize any acid which may exist in the stomach, but so to regulate the process of digestion, as to prevent its formation; and it has been found, that it may be taken for months or years if necessary, without producing any kind of injurious effect. An irregular state of the alimentary canal is almost a constant attendant upon Dyspepsia, and although it generally produces constipation, it occasionally manifests itself in the opposite state of diarrhœa. Except in very protracted cases, or where there is reason to suspect some structural derangement, this symptom generally yields to a cautious exhibition of purgatives, together with a due attention to the state of the diet; and without any specific treatment the bowels acquire their proper tone, as the system returns to its healthy state. Astringents we conceive to be seldom necessary, and for the most part injurious; diaphoretics, particularly opium combined with ipecacuanha, are frequently found beneficial, and this may be regarded as the best form of giving opium, where pain or any other symptom indicates its employment; it must always be preceded or accompanied by mild purgatives.

Sect. II. *Diabetes.*

Next to Dyspepsia we have placed Pyrosis and Pica in our list of diseases, which depend upon a defect of the digestive organs; the former of them consisting in the eructation of a watery fluid from the stomach, attended with pain, heart-burn, and flatulence; the latter in a species of perverted appetite, by which the patient is seized with an almost unconquerable desire of eating indigestible substances, that are not properly articles of food. Although these are usually considered by systematic nosologists to be distinct diseases, and occasionally occur almost unconnected with any other symptoms, yet we are induced to regard them as mere modifications of Dyspepsia; and, with respect to their treatment, we have little to offer in the way of general principles that has not been stated in the preceding section. We shall merely remark that Pyrosis is generally supposed to originate from the habitual use of an indigestible diet, which must of course be attended to in the cure, and that Pica is commonly found to be connected with a torpid state of the uterine system, as well as of the digestive organs.

The next disease which we have placed in this division is Diabetes, an affection of a very peculiar nature, and which, both with respect to its origin, its proximate cause, and its treatment, has given rise to much controversy. Its most remarkable symptoms are, a great increase in the quantity of urine, a voracious appetite, a stoppage of the cutaneous perspiration, thirst, emaciation, and great muscular debility. The urine is not only prodigiously increased in its quantity, but likewise has its composition completely changed; the substance named urea, which it contains in the healthy state, is entirely removed, or exists in very small proportion, while in its stead we find a large quantity of a body possessing the physical and chemical properties of sugar. Whether diabetic differs essentially from vegetable sugar, is to be regarded more as a chemical question, than as what in any respect influences either our pathology or our practice; and it has been a subject of controversy whether there be a proper Diabetes insipidus, that is, a disease attended with the increased discharge of urine, the voracious appetite, and the morbid state of the skin, but where the urine does not contain sugar. There is much obscurity respecting the origin of Diabetes; it has been attributed to improper diet, to the use of spiritous liquors, to large quantities of watery fluids, to exposure to cold during perspiration, to violent exercise, and, in short, to any thing which might be supposed likely to weaken the system generally, or the digestive organs in particular. It does not, however, appear that any of these circumstances so commonly precede the disease, as to entitle it to be regarded as the cause, although many of them may contribute to aggravate it, or bring it into action, when the foundation is laid in the constitution. The proximate has been no less the subject of controversy than the exciting cause, and on this point two hypotheses have divided the opinions of pathologists; some have ascribed it to a primary affection of the stomach and the function of assimilation, and others to a primary disease of the kidney. Upon the whole, we conceive that the former is by far the most probable supposition; for although the examination of the body after death has detected a morbid state of the kidneys, this we should ascribe to the great alteration in the quantity and quality of the fluid which passes through them, rather than have recourse to the idea, that any change in the secreting vessels of the kidney could produce such a complete perversion of the actions of every part of the system.

Diabetes has, of late, occupied an unusual share of the attention of medical men, in consequence of the circumstances connected with its treatment appearing to coincide with some pathological doctrines which were fashionable a few years ago. The remarkable change in the chemical condition of the urine, by which a compound, consisting of hydrogen and carbon is substituted for one into which azote enters as a principal ingredient, led to the idea, that by excluding these elements, as much as possible, from the diet of the patient, the morbid state of the fluid might be prevented or corrected. It was accordingly found that, by employing a complete animal diet, the sugar was no longer produced; and it was announced that, by strictly adhering to this regimen, the disease had been completely cured. Subsequent experience has not, however, confirmed these favourable reports, for although, while the hydrogen and carbon are no longer present in the digestive organs, the sugar can be no longer generated, yet the diseased action seems to remain without alteration, so that, upon the least deviation from the animal diet, the saccharine urine is reproduced, at the same time that the patient remains nearly in his former state of debility, without any considerable abatement of the other symptoms; so that, although the progress of the complaint be retarded, it does not appear that it ever has, by this means, been ultimately counteracted. A very different mode of treatment has been since proposed, and even adopted in Diabetes. Notwithstanding the apparent failure of the muscular powers, and the different circumstances indicating the extreme of debility, very copious bleedings have been employed, and if not with much benefit, at least without that aggravation of the disease which might have been apprehended. The old method of treating the complaint, and the one which is still often had recourse to, is by astringents of various kinds, to which opium is often conjoined; and of the efficacy of this practice we have many flattering accounts, but, from its total failure on other occasions, we suspect that the alleged cases have either not been proper Diabetes, or that the medical attendants have hastily caught at some flattering appearances of amendment, and mistaken them for a radical cure. Upon the whole, we believe that where the urine was in large quantity and highly saccharine, where Bulimia existed in any considerable degree, and where the cutaneous perspiration was abolished, no cure has ever been accomplished. With respect to the treatment which may afford the best chance of success, or which may possibly remove the complaint in its incipient state, we should recommend that a moderate bleeding be premised, and that a diet be employed, of which vegetable matter should form only a small proportion; at the same time we may administer vegetable tonics, and may endeavour to restore the natural action of the skin by diaphoretics and the warm bath.*

Sect. III. *Podagra. Gout.*

Gout may be characterized as a disease which recurs in paroxysms, consisting essentially in the pain of one or more of the smaller joints of the hands or feet, most commonly of the great toe, which is attended with fever, and terminates in redness and swelling of the

* The weight of testimony is unquestionably in favour of the theory that Diabetes primarily depends on a diseased action of the digestive organs, or a want of tone in the assimilating powers of the system; the kidneys are secondarily affected. Of the causes which induce an impaired state of the stomach, intemperance in the use of ardent drinks is the most common. The most successful treatment of Diabetes is that originally proposed by Sydenham; the use of animal food and abstinence from vegetable substances. Ferriar judiciously prescribes, besides animal food, various tonics, as bark, bitters, chalybeates, &c. (See Med. Hist. and Reflect. vol. iv.) In a late case, the writer has removed the disease by the use of animal food alone.

Hosack.

part; the local affection is preceded by a state of general indisposition, and especially by various dyspeptic symptoms; and we usually find that, when the inflammation is established in the extremities, the stomach becomes relieved. The paroxysms come on at uncertain intervals, and frequently without any obvious exciting cause; but it is generally connected with an hereditary predisposition, and is scarcely ever met with except among persons in the higher ranks of life; and for the most part, when not hereditary, may be clearly traced to habits of luxury and self-indulgence. When Gout exists in a well marked form, there is no difficulty in distinguishing it from all other affections; it is easily recognized by the state of the stomach, the part which is affected, and the nature of the predisposing and exciting cause; but in its more irregular forms, it is apt to be confounded with Rheumatism, and it appears, indeed, that the two diseases are sometimes combined in the same patient. In those who are predisposed to Gout, it may be excited by any thing which produces an increased action in the part, as by excessive exercise, by a strain, or a bruise; but in those who inherit the disease, or who have once suffered severely from it, we often find it impossible to detect any assignable cause for the paroxysm. The fact that Gout never attacks the poor, while even a considerable proportion of the wealthy are more or less subject to it, is known to every one, and has necessarily given rise to much speculation respecting both its predisposing and its proximate cause. It is not very easy to determine to which of the circumstances that attach to the condition of the rich its production is to be attributed; mere excess in eating, although it produces stomach complaints, does not generate that specific state of the digestive organs which gives rise to Gout, nor do we find that the abuse of fermented or spirituous liquors, which is so common among the lower classes, subjects them to this complaint. It would appear that it depends upon the combined operation of luxurious habits of various kinds, of which, indulgence in the gratifications of the table, and the want of a due quantity of bodily exercise, are probably the most important.

Besides the regular forms of the disease, where it occurs in paroxysms, that alternate with, or succeed to complaints of the stomach, and leave the patient in perfect health during the intervals, there are other varieties of the disease, in some of which the different stages exhibit considerable irregularity, both with respect to their degree of violence, and the order of their succession; in one of these, which is called retrocedent, or repelled Gout, after the disease has settled upon the joints of the extremities, it suddenly leaves the part, and attacks some of the internal viscera, the brain, the lungs, the heart, or the stomach; and, if not relieved by the appropriate remedies, may suddenly prove fatal, by preventing these organs from performing their ordinary functions. The regular Gout is not a disease which is usually considered as productive of danger to the life of the patient; but it materially impairs his comforts and utility, for the fits generally increase upon him, both in their violence and their duration, so that at length he is doomed to pass a considerable part of his time under their influence, while the joints, by the repeated attacks of inflammation, become distorted, or nearly immoveable. The irregular Gout, although productive of less urgent symptoms, and of little or no injury to the joints, has the effect of imbittering the life of the patient, by an almost constant state of indisposition; and it has a peculiar tendency to induce a distressing lowness of spirits, and a feeling of despondency, which are more intolerable than acute pain.

The phenomena of Gout were formerly regarded as affording the most direct evidence of the theory of the humoral pathologists, in which a morbific matter exists in the fluids, is capable of being conveyed from one part of the body to another, and manifesting its presence in them by its appropriate symptoms. Palpable, however, as this conclusion was conceived to be, the modern pathologists have denied the existence of this morbific matter, of which it has been said that no evidence exists, except what is derived from the symptoms of the disease; and these, they have asserted, might be better explained upon other principles. The researches of the modern chemists have, however, given some plausibility to the doctrine of the humoralists, by discovering that gouty urine contains an unusually large proportion of lithic acid; and as the same substance has been found exuding from the joints, in combination with soda, it would seem to follow, that the general mass of the circulating fluids are impregnated with it. But although the fact must be interesting, both in a pathological and a practical point of view, it cannot be considered as throwing much light upon the proximate cause of Gout, as we have still to inquire how the presence of the lithic acid can produce the peculiar affection of the stomach, why it is transferred from the stomach to the joints, why it particularly attacks the small joints of the extremities, why the general and local symptoms alternate with each other, and, in short, what connexion or relation it bears to the ordinary symptoms of the disease.

The treatment of Gout has varied very much at different times, according to the prevalence of particular medical theories, or the pathological doctrines that have been entertained respecting the nature of the complaint. While all diseases were regarded as salutary efforts of nature, the paroxysm of Gout was considered rather as a curative operation, which was to be induced or promoted by the practitioner, than as a morbid condition of the system which it was his business to remove. Accordingly, all our attempts were more calculated to increase, than to diminish the inflammation of the joints, by the application of warmth, and by the use of stimulating diet and medicines; and even during the intervals of the fits, so great was the apprehension of the mischief that might arise from checking the efforts of the *vis medicatrix*, that nothing was attempted more than a mere palliative plan, which was generally altogether inert. Of late, however, we have ventured upon a more active practice, and we have not hesitated to oppose the regular progress of the disease, or even to counteract the natural actions of the system. We administer brisk purgatives to clear the alimentary canal, we attempt to moderate the inflammation of the joints, if not by the application of cold, at least by the abstraction of heat; and we occasionally employ bleeding, either general or topical, and enjoin the strict antiphlogistic regimen. To what extent this plan is to be pursued, must be left to the discretion of the practitioner, as determined by the urgency of the case; while we have ample evidence of its safety, when judiciously employed, we are to bear in mind that the inflammation of Gout is of a specific kind, and that the immediate danger of the disease consists in its being repelled from the extremities to the internal viscera. After we have carried the depleting system as far as is thought proper or necessary, opium, either alone, or in combination with ipecacuanha, will be found useful for removing irritation, and bringing back the functions into their ordinary state. When the fever and inflammation have subsided, we shall probably find a course of bitters and stomachics necessary to strengthen the digestive organs, and to prevent the recurrence of that state which lays the foundation for future attacks of the disease. But this object, which is even of greater importance than the cure of the individual paroxysm, is to be attempted more by regulating the habits of the patient, than by the employment of any particular article of the materia medica; provided the constitution be not too much impaired, and the alteration be not too hastily adopted, we find that, by exchanging a life of gluttony and indulgence for one of temperance and activity, we are generally able o accomplish the desired effect. Simple however, as this plan may appear, it is but seldom that the practitioner is able to put it into execution; for so wedded are the patients to t eir accustomed indulgencies, that they shut theirs ears to the salutary counsels of their medical attendants, and voluntarily resign themselves to pain and disease, in preference to health and comfort, when they are to be purchased by the renunciation of their luxurious habits.

An important circumstance yet remains to be noticed respecting the cure of Gout, the discovery of a medicine which is supposed to have a specific effect upon the disease, so as to remove it by a kind of operation which we cannot refer to any general principles. The medicine was introduced into practice in the form of a secret recipe, but it appears to be ascertained that its essential ingredient is the colchicum autumnale. This is one of those substances which, when taken in a large quantity, prove highly deleterious; but in moderate doses, it may be taken without danger, and usually operates by producing an evacuation either from the bowels, the kidney, or the skin. It affords almost a unique example of a remedy being introduced into practice under an empirical form, which maintained its reputation after its composition had been detected; for we seem to be in possession of the most unequivocal evidence of its power, both in preventing and removing the gouty paroxysm. Sometimes the salutary effect ensues without any sensible operation, but generally the benefit is more apparent, and there is supposed to be less danger of any deleterious action on the vital powers, when some kind of evacuation has taken place. Cases have occurred, in which, by giving the medicine in too large a quantity, or in an improper state of the system, it appears to have produced almost the immediate destruction of life; but by using the proper precautions, we conceive that the colchicum may be administered with safety and advantage.*

Sect. IV. *Cachexiæ. Scrofula.*

In the order of the Cachexiæ we shall find some of the most formidable diseases which attack the human frame, both from the extent of the mischief which they occasion, and the little power which our remedies possess over them. The first that we shall notice is Scrofula, to which, as indicating its pre-eminently baneful influence, the name of *evil* has been popularly applied. The term scrofula has, we think, heen used in too vague a manner, so as to include a variety of anomalous affec-

* This section on Gout deserves great consideration. The writer of this note is induced to insert here his views on this disease, though previously before the public. 1st, Gout is not an hereditary disease, in the sense in which it is usually considered; it is only hereditary as far as fortune, and its attendants, ease, luxury, habits of intemperance both in eating and drinking, and that predisposition which arises from a strong and vigorous constitution, are hereditary. 2d, Gout takes place for the most part in the sanguine temperament, in the plethoric habit of body, and is exclusively an inflammatory disease of the whole system, as well as of the part affected. 3d, Its associate or vicarious diseases, Apoplexy, Palsy, Angina Pectoris, Asthma, habitual Catarrh, Eruptions on the Skin, Obstructed Viscera, and Dropsy, arise from the same habit of body, and from the same causes. 4th, The deposits of saline or earthy matter, which take place upon the joints, in Gout and Rheumatism, in the kidneys and bladder, occasioning Stone and Gravel, in the brain of apoplectics, in the arteries of persons advanced in life, in the coronary vessels and valves of the heart, have the same common origin, and these extravasations are usually the effects of an overloaded state of the blood-vessels. 5th, Although the same earthy or saline materials exist in the blood in a state of health, and are constantly passing off in our excretions, they are in no instance the cause of Gout; but when deposited upon the joint, in that disease, or upon other parts of the body, such deposits are the effects of plethora, the parent of both. 6th, The *predisposing* causes of Gout are, the excessive use of wine, ardent spirits, animal food, the condiments of the table, and the neglect of the exercise necessary to counteract their effects upon the constitution; while the check of the excretions by the cold of autumn and winter, or the sudden impetus given to the circulation by the returning spring, proves the most usual exciting cause of this disease. Hence we find that Gout, like Rheumatism, and other inflammatory diseases, the attendants upon autumn, winter, and spring, are but rarely to be met with in the summer season, when our diet consists of a large proportion of vegetable food, and the excretions, especially by the surface, are most abundant: hence, too, it is observed, that persons who are remarkable for their excessive discharges by the skin are rarely the subjects of Gout, even though the usual causes of this disease are, at the same time, indulged in to a great degree. 7th, As the causes of Gout are *intemperance* and *indolence*, the best means of preventing this disorder may be summed up in their immediate antidotes, *temperance* and *exercise:* but where the patient has not resolution enough to withstand the temptations of the table, and is unable to take the necessary exercise, the occasional evacuations by the lancet, and other means of diminishing the fulness and excitement of the vessels, should be employed. 8th, The most effectual means of removing the inflammatory action attendant upon the first stage of the paroxysm of Gout, consist in depletion by the *lancet, cathartics*, and such remedies as operate by restoring the excretions from the surface of the body, the physician paying due regard, in the use of these means, to the constitution of the patient, his time of life, and season of the year In correspondence with the use of these remedies, both the diet and regimen of the patient should be simple, and strictly antiphlogistic. 9th, During the febrile stage of the paroxysm, the part or parts affected should be lightly covered with soft flannel, or carded cotton, for the purpose of soothing the existing irritation, and of promoting a perspiration from their surface: the practice, however, of loading the limb with the accustomed strata of flannel, and thereby of adding to the heat and inflammation of the parts, and also that of applying cold water, or other cold applications, to the affected limb, are alike prejudicial and dangerous, and are equally to be reprobated. 10th, At the termination of the febrile or inflammatory stage of Gout, as of other inflammatory diseases, the same means of restoring the tone of the system are indicated; viz. chalybeates, bitters, the moderate use of animal food, wine, porter, exercise, and, in the summer, sea-bathing. The eau medicinale of Husson has not maintained so high a character as a remedy for Gout in this country as in Europe. (See American Med. and Philos. Register. Thomas's Practice, 5th Amer. edition.)

Hosack.

tions, which have little connexion either in their seat, their symptoms, or their termination. We conceive that it ought to be restricted primarily to an affection of the absorbent glands, producing, in the first instance, enlargement, with some degree of inflammation, afterwards a hardened or compacted state of them, in which they are no longer able to exercise their appropriate functions; and, lastly, an ulceration, attended with a peculiar train of symptoms, which sufficiently distinguish it from all other inflammatory affections. Scrofula is a disease which especially attacks certain constitutions or habits of body; the subjects of it are generally persons of fair skins and smooth complexions, and frequently possess great delicacy of feeling and brilliancy of mental powers, indicating what has been termed the sanguine temperament. Its first invasion is during childhood; it is most severe about the period of puberty; and after the adult age, if the frame can bear up so long against its ravages, it gradually declines. It usually makes its first appearance in the glands of the neck, where it forms large ragged ulcers, that are very difficult to heal, but which are often productive of no inconvenience, except the unsightly scars which they leave behind them. It has indeed been supposed, that the discharge from these ulcers is favourable to the general health, by giving vent, as it were, to some humour, which otherwise might produce more dangerous consequences, by affecting some vital organ; but this opinion we are disposed to regard as derived from a false theory, and as not sanctioned by experience. Other glandular parts are, however, often affected, which are more concerned in the exercise of the vital functions, of which those of the mesentery, or other parts more immediately connected with the vital organs, are the most important. When these become the subjects of Scrofula, they prove destructive to health, by preventing the due supply of chyle, and induce a species of atrophy or tabes, which is characterized by a hard and tumid abdomen, and by the extreme emaciation of the face and extremities. It is under this form that Scrofula proves fatal.

It is now generally agreed that it is not a contagious disease; that it is endemic in those countries which have a damp and cold atmosphere; that its exciting cause is improper food, impure air, want of exercise, and a deficiency of clothing; and that these causes act the most powerfully upon the individuals who are predisposed by an hereditary taint, or by previous weakness, but from the influence of which probably no one is entirely exempt. We have stated Scrofula to consist essentially in a disease of the absorbent glands, and we believe that, in every instance, its commencement may be traced to an affection of these organs, but it frequently happens that in the progress of the complaint, glands of other descriptions become diseased, and even parts which are not glandular; two of the most frequent of these varieties are certain affections of the eyes and of the bones. How far these should be strictly called Scrofula, or whether they might not, with more propriety, be considered as distinct diseases brought into action by Scrofula, is a question we shall not now discuss. The same remark applies to the lungs, the glands of which likewise frequently become affected in Scrofula, and give rise to the fatal disease of Phthisis pulmonalis; but this affection is one of so much importance, and is characterized by so many peculiar symptoms, that whatever may be our opinion respecting its nosological character, we must make it the subject of a distinct section.

Many hypotheses have been formed respecting the proximate causes of Scrofula, but we are disposed to think, that they have thrown no real light either upon its nature or its treatment; indeed, with respect to the latter circumstance, we conceive that the doctrines of the humoral pathology, which taught that Scrofula depended upon a morbific matter existing in the blood, which was to be corrected or removed by rigid abstinence, or by a long continued course of purgative medicines, was often productive of serious injury. Indeed the management of Scrofula, although so frequently an object of the greatest interest to practitioners, is a point concerning which the art of medicine has yet made but little advance, and respecting which we are still left in a state of great ignorance and uncertainty. It is inde[illegible] sufficiently ascertained that our great object must b[illegible] improve the general health, and every one will se[illegible] propriety of carefully removing the exciting [illegible], where it can be ascertained, but beyond this [illegible] we have little upon which we can build wi[illegible] degree of confidence. Whether it be the [illegible] the effect of the scrofulous disposition, a deranged state of the alimentary canal is a usual attendant upon the disease, so that purgatives will be frequently found a necessary part of our treatment; and in that variety, where the mesentery is peculiarly affected, the torpor of the bowels often makes it necessary for us to employ the most powerful drastics. The weakness of all the vital powers, which characterizes the scrofulous constitution, suggests the employment of tonics; and they have accordingly, under some form or other, generally made a part of every plan that has been proposed for the cure of the disease; but the peculiar disposition to inflammation which belongs to the sanguine temperament, and the liability which local inflammation has, in those predisposed to it, to assume the scrofulous aspect, always renders their employment critical. This remark applies particularly to cinchona and iron, which, under various forms, have been long prescribed as the grand remedies for this complaint, but which, although they may be beneficial in certain states, where the system is exhausted by long continued disease, probably possess no specific power in counteracting the scrofulous action, and seem but little adapted for the constitutions which are the most disposed to its attacks. In a chronic affection, and in one of so general an operation, we are naturally led to regard the effect of diet as an important agent in the re-establishment of the health; yet on this point very opposite plans have been adopted in the disease now under consideration, for, while a strict antiphlogistic system has been strongly enforced by some practitioners, others have equally insisted upon the importance of a nutritive and even a stimulating regimen. Both these extremes we believe to be injurious, and on this point, as well as respecting the articles of the materia medica, we have perhaps no more explicit rules to guide us than that every thing should be directed towards the establishment of the general health; if the patient be languid and emaciated, we are to supply him with as much nourishment as the digestive organs will admit; but if, on the contrary, he be of an inflammatory habit, we must proceed, although with caution, on the opposite system. The use of sea air, of sea bathing, and of the cold bath generally, respecting which so much had been said in Scrofula, may all be referred to the same principle. To the inhabitants of large towns, who generally pass their time in close apartments, and are immersed in smoke and impure air, the freshness of the sea breezes must be highly salutary; but we apprehend that there can be nothing of a specific nature in the air of the sea, and that many inland situations are even preferable, as being less liable to dampness and moisture. For bathing, however, salt is perhaps always preferable to fresh water, and it has been supposed that sea-water has a beneficial effect upon scrofulous ulcers as a local application, although the evidence for this opinion be not very decisive. In speaking of the remedies for Scrofula, we must not pass by in silence the alleged virtues of mercury, and especially of calomel, which has been held up as a kind of specific in that variety of the disease, where we suspect there to be a scirrhous state of the mesenteric glands. How far mercury, in any form, possesses the power of resolving glandular tumours, we are scarcely prepared to decide, but we are much disposed to refer a great share of the benefit which has been gained by the use of this medicine merely to its power in promoting the operation of the purgatives with which it is usually combined. With respect to all the specifics that have been proposed for Scrofula, the acids, alkalies, earthy and metallic salts, and various vegetable extracts, we confess that we are extremely sceptical as to any benefit that has ever been derived from them. The management of the local affections, whether scirrhous glands, ulcerations, enlargement of the bones, or in whatever form the disease makes its appearance, falls under the especial province of surgery; we shall only remark concerning it, that their treatment appears as difficult and uncertain as is the constitutional form of the disease; and that notwithstanding the numerous plans that have been brought before the public with so much confidence, the cure of these complaints must still be considered as one of the great desiderata of the art.

SECT. V. *Phthisis pulmonalis. Pulmonary Consumption.*

We have already referred to this complaint in the preceding Section, and have noticed its probable connexion with Scrofula; but, whatever be our opinion on this point as a pathological question, it is a disease which amply deserves to be made the subject of distinct consideration. It is characterized by pain in the side or the chest, attended with cough, dyspnœa, and with expectoration, which, as the disease advances, becomes purulent. A febrile state is induced, which ultimately terminates in acute hectic, while in the latter stages there is colliquative diarrhœa and profuse perspiration, attended with excessive debility and emaciation. Although persons of the sanguine temperament are the most subject to this affection, yet it shows so powerful an hereditary tendency, that the children of phthisical parents, whatever constitution or temperament they may possess, and whatever may be their apparent vigour, are always liable to its attacks. Its exciting cause is in most cases to be traced to some circumstance which produces inflammation in the lungs, although, where there is a decided hereditary disposition, it is often very difficult to assign any immediate cause for its invasion. A great proportion of all the cases appear to originate from Catarrh, so that, in our moist and variable climate, where the excess of civilization and refinement has tended to diminish the vigour of the natural constitution of the inhabitants, and where many of the modes of life are peculiarly adapted to render the body liable to suffer from the state of the atmosphere, Phthisis may be regarded as the great scourge of the island. It has been calculated that not less than 55,000 persons are annually destroyed by it, which, if we estimate the total population of England at 12,000,000, will not be very far short of $\frac{1}{2000}$ part of the whole population. When the disease exists in its fully formed state, its character is too well marked to admit of much doubt or uncertainty; but as it often comes on in a very gradual manner, and supervenes upon the affections of the chest, it is sometimes difficult to decide upon its presence. The circumstance which has been usually had recourse to, as forming the diagnosis, is the state of the expectoration, whether it be mucous or purulent; but as this is a point which cannot itself be, in all cases, very easily decided, various tests have been employed for this purpose. Upon the whole, however, we conceive that an attention to the general condition of the patient, to his previous constitution and hereditary disposition, are more important than any one symptom, and will generally enable us to form a correct judgment. Although the state of the lungs in Phthisis has been carefully examined, and the appearances which they exhibit very minutely detailed, there still remains much uncertainty respecting the nature of the proximate cause, or of the manner in which the exciting causes produce the change of structure which the parts experience. When we examine the lungs after death, we find them to be filled with hard tumours, called tubercles, which seem to be composed of indurated glands; these are at first of an indolent nature, but they acquire the inflammatory state, and proceed to suppuration, when the hectic fever comes on, and the disease assumes its characteristic features. We have already spoken of the connexion which there appears to be between Scrofula and Phthisis, and the morbid appearances in the lungs may seem to confirm the idea of the connexion; it must, however, be acknowledged, that the two affections do not bear any exact ratio to each other in the same individual, and even that some whole families are more disposed to Scrofula, and others to Phthisis.

With respect to the treatment of Phthisis, we have little to offer, except a melancholy narrative of the failure of all the plans that have been presented to the public. Indeed, to those who have witnessed the condition to which the lungs are reduced, after they have experienced the ravages of this complaint, it can excite no surprise that all attempts at cure should be entirely unavailing, and must impress the mind with the full conviction that it can only be in the very earliest stages that any relief is to be obtained from the interposition of medicine. It is therefore to the *prevention* of Phthisis rather than to its *cure* that we are to direct our efforts, and this, if it can be accomplished, must depend upon avoiding the exciting causes, especially cold and moisture, and still more, by using every means for fortifying the body against their influence. Warm clothing and airy rooms, moderate exercise, regularity in diet and in all the habits of life, may do much in preventing the extreme susceptibility to catarrh, but for those whose situation will admit of it, and who are disposed to make so great a sacrifice, the removal to a warmer and more settled climate, is the only effectual preventative. How far this is to be advised when the disease has actually established itself, or what stage of Phthisis admits of a chance of cure by this means, is a question on which it is extremely difficult to decide; and there is no point concerning which a practitioner feels a more painful duty imposed upon him, than to pronounce the doom of his patient to be irrevocable, by discouraging his removal, or to subject him to a more painful fate, by separating him from the comforts of his home and the attentions of his friends, without a prospect of relief. In the earlier stages of Phthisis, or where the disease is impending, without the lungs being actually disorganized, our great object is to prevent or counteract inflammation, and yet this must be done in such a way as to diminish the strength in as small a degree as possible. General blood-letting is sometimes admissible, but it must be always had recourse to with caution; we may with less hazard employ topical bleeding, if the pain of the chest and state of the pulse seem to indicate it, and still more blisters, which are perhaps the most powerful remedies that we possess in this disease. We must endeavour to allay the cough by mucilaginous mixtures, to which small quantities of opium may be added, and we may endeavour to allay the fever by diaphoretics; but we must proceed with great caution in the administration of any substance that is intended to act upon the capillaries of the skin, in consequence of the tendency to profuse perspiration, which always exists in the latter stages of Phthisis; the same remark applies also to the bowels. How far any benefit is to be expected from sedatives is still a controverted question; for although we apprehend there can be no doubt of the advantage which is occasionally derived from digitalis, in certain inflammatory states of the chest, yet we are not disposed to expect much from it where the structure of the lungs is affected. As, however, we have no means of ascertaining when this crisis has actually occurred, a cautious employment of digitalis may be generally admissible; but it should always be given in small doses, and we think it may be assumed as a general principle, that if no benefit be obtained from small doses of this medicine, we are not to hope for any advantage by increasing the quantity; on the contrary, we should expect that its deleterious operation would be induced, with all its train of distressing consequences. When the hectic is fully established, nothing is to be attempted but the palliative treatment, and for this we must refer to the remarks that we have already offered on the subject. It only now remains for us to sooth the termination of life, by diminishing, as far as lies in our power, the various sources of uneasiness that from time to time rise up to distress the patient. Every candid practitioner will confess, that beyond this, he can have no expectation of obtaining the least relief from the aid of medicine; and it is a duty which he owes to himself no less than to his patient, to refuse his consent to any of those experiments, which, with whatever pretensions they may be supported, must be regarded as the offspring either of delusion or of empiricism.*

Sect. VI. *Rachitis. Rickets.*

Another disease, which, like Phthisis, is supposed to be nearly allied to Scrofula, if not to be a mere modification of it, is Rickets. It would seem to have first made its appearance in modern times, for it is too remarkable in its symptoms to have been overlooked; and there is probably some reason to believe that it is not now so frequent as it was half a century ago. It is essentially a disease of the bones, in which they increase in bulk, and at the same time lose their firmness, so as not to bear the weight of the parts attached to them without being bent out of their natural form. It makes its first appearance at an early age, and continues until about the period of puberty. During this interval the patient suffers from the immediate effects of the distortion that is produced in various parts of the body, as well as from irregularity in the different organic functions, and especially in those of the digestive organs, so as to induce a great degree of emaciation and debility, which not unfrequently affect the mental

* The causes of Pulmonary Consumption are not exactly the same in this country and Great Britain. With the increase of manufacturing establishments in England we find an increase of the evils which induce pulmonary disorders, and of these evils scrofula may properly be considered among the principal. In the United States scrofula is comparatively little known; but, while we admit the influence of particular employments and modes of living, in inducing consumption, this disease, in most instances in this country, may be ascribed to the sudden vicissitudes we experience in this climate, especially on the sea-board; to imprudence in dress, and improprieties in the use of ardent drink, and other species of dissipation. A common catarrh, especially if frequently renewed, may be placed at the head of the causes of the disorder in this country: it is one of those causes, too, which, while it attracts the least attention, commonly does the greatest mischief. Pulmonary consumption has little association with hæmoptysis. Indeed, this form of disease is far more frequently preceded by catarrhal and pneumonic inflammation than by hæmorrhage from the lungs; and even in those cases where hæmoptysis precedes pulmonary consumption, inflammation of the lungs is usually antecedent to both, and demands the early attention of physicians.

The inflammatory character of pulmonary consumption cannot be too constantly kept in view, and the treatment indicated for the removal of other inflammatory affections of the chest will be found to be most successful in this more insidious disease. In the Quarterly Reports on the disease of the city of New-York the writer has already noticed the point of practice. "We have in many instances employed blood-letting with the most happy effects, in many cases of incipient *Phthisis*, even where strong hereditary predisposition existed. Indeed we are induced, from some late observations on the subject, to express the opinion, that in the commencement of Phthisis, as in peripneumony, blood-letting is not sufficiently employed, but is too frequently neglected until the inflammation has so far extended that suppuration becomes inevitable. Nor do physicians in general appear to have been sufficiently attentive in describing the symptoms characteristic of the first or inflammatory stage, and consequently have been regardless of that active antiphlogistic treatment which alone can prevent the tuberculous or suppurative stage. In as much as suppuration, or a purulent secretion from the lungs, necessarily implies preceding inflammation, we conceive too early attention cannot be given to the premonitory symptoms which announce the inflammatory stage, but which are frequently so inconsiderable, being seated in the less sensible, the cellular portion of the lungs, that both physician and patient are alike regardless of the present symptoms, and of the consequences to which they lead. Instead, therefore, of trusting to syrups, anodynes, pectorals, ptisans, or the Iceland moss, to allay the hacking cough and pains in the chest, which indicate the first approach of the disease, we earnestly recommend the same active treatment, by blood-letting, blisters, and other means of diminishing excitement, as are employed in the treatment of a pleurisy, or any other acute inflammation; and we could add, in confirmation of this view of the subject, many recent cases, in which the practice here recommended has been attended with the most beneficial results." *Amer. Medical and Philosophical Register.* See also *Rush.* Thoughts on *Pulmonary Consumption.*

Hosack.

as well as the corporeal faculties, and ultimately proceed to a fatal termination. When the disease assumes a less acute form, the powers of the constitution finally overcome the violence of the disease; but the deformity of the bones still continues; and when it has affected the trunk of the body, it often materially deranges some of the functions, and leaves the parts in a state from which they can never afterwards recover themselves. The cause of Rickets is not yet ascertained; many of the circumstances which tend to induce Scrofula seem also to favour the appearance of Rickets; but we are disposed to regard them as distinct complaints, because we do not perceive that the symptoms are necessarily connected together; but, on the contrary, that they commonly attack certain individuals separately, and are not convertible into each other. The affection is generally thought to be hereditary, yet the tendency is not so obvious in this case as in Scrofula, or in Phthisis; and we perpetually observe examples, where a single member of a family is diseased without any other suffering from it. The proximate cause of Rickets appears to be a change in the physical and chemical constitution of the bones, the animal matter which enters into their composition being probably in a morbid state, and the earthy matter either deficient in quantity, or altogether wanting; but in what way these changes are effected, or how they follow from the exciting cause, we are altogether unable to explain.

We have very little to offer respecting the cure of Rickets, more than that we must adopt every means which lies in our power for removing the supposed exciting causes, and for promoting the general health. The disease seldom exhibits any inflammatory symptoms, so as to render bleeding necessary; but the derangement of the digestive organs, and the torpor of the alimentary canal, make purgatives an essential part of the treatment. To these tonics and stimulants may be occasionally added; but we do not conceive that any great benefit is to be derived from them, unless where the appetite is particularly defective, and when the bowels are brought into a natural state. Still less confidence do we place in any of those remedies, which have been from time to time offered to our notice, as possessing a specific effect in Rickets, such as phosphate of lime, upon the principle of supplying the deficiency of this substance in the bones, or the carbonate of ammonia, for neutralizing the supposed acid in the blood,—remedies which we believe will be found as useless in practice as we apprehend them to be incorrect in theory. It is a difficult point to determine upon the means that ought to be adopted for counteracting the mechanical deformity that arises from the state of the bones. Perfect rest in the horizontal posture has been recommended; but in very young children this is almost impossible to be strictly adhered to, while the want of exercise is itself a means of increasing the tendency to disease; nor indeed does it appear, that, with all our care, we are able to prevent the bones from being distorted by the action of the muscles that are attached to them, or by the weight of the different parts pressing upon each other. Upon the whole it may be desirable to recommend the horizontal in preference to the erect posture during a part of the day; but we should not sacrifice to this system, the benefit that may be supposed to arise from the general salutary influence of air and exercise. It appears to be agreed, that the mechanical contrivances for supporting or straightening the limbs are not of much use in Rickets.

Sect. VII. *Syphilis.*

The treatment of this disease is considered as rather falling under the province of the surgeon than of the physician, yet it offers so many curious subjects for speculation, and involves so many interesting questions of pathology, that we cannot pass it by in our system, although exclusively appropriated to the practice of medicine. Notwithstanding Syphilis is a disease of the most frequent occurrence, and one that has engaged the attention of medical men for some centuries, there are many very important points respecting it which still remain undecided. The first accounts that we have of the unequivocal symptoms of Syphilis appeared about the end of the 15th century; but how it was produced, or from what quarter of the world it proceeded, are not yet correctly ascertained. The disease, in its ordinary form, is communicated by the actual contact of parts previously infected, which necessarily happens most frequently to the generative organs, and, independently of their situation, it is probable that their structure, as possessing a surface covered by a thin cuticle, and furnished with secreting glands, is peculiarly liable to receive the infection. The first symptom is a local ulcer, to which the name of chancre has been applied, and which seems to be altogether a local affection; but it is a property of the chancre to generate contagious matter, which is capable of being absorbed, and of contaminating the system at large. Besides the local syphilitic ulcer or chancre, there is another form of venereal infection, in which, without any wound or breach of the cuticle, a mucous, or secreting surface, becomes inflamed, and exudes a large quantity of semi purulent matter, which has the property of inducing the same state on a similar mucous surface with which it is in contact; to this the name of Gonorrhœa has been applied. It has been a much disputed question, in what manner these two affections are related to each other, whether they are distinct diseases, or whether they originate from the same poison having experienced some modifications, or assume a different aspect from the different nature of the parts to which it is applied. Upon the whole, perhaps the most decisive facts are in favour of the diversity of the two diseases; but, at the same time, we must remark, that some authors of the first eminence profess the contrary opinion. It would be inconsistent with the brief and general view which we profess to take of the subject, to detail all the symptoms of this proteiform disease, which, as it affects a great variety of parts and structures, and attacks indiscriminately all constitutions and temperaments, exhibits a greater diversity of appearances than perhaps any other complaint to which the human frame is obnoxious. If the local ulcer be not cured by the appropriate remedies, and if means be not taken to prevent the contamination of the system, a portion of the infectious matter is taken up by the lymphatics, and seems to be carried into the mass of the circulating fluids. In its passage along these vessels it usually affects some of the glands, producing in them tumours, which are styled buboes, and afterwards abscesses, which partake of the same infectious nature with the original chancre, and still farther contribute to the general diffusion of the disease. When the system becomes in this manner completely contaminated, there are certain parts of the body which are peculiarly disposed to manifest the presence of the poison, and in these it exhibits itself in a uniform order of succession. It first appears in the mucous membrane of the throat and fauces, producing an inflammation and superficial ulceration, which terminates in an erosion and loss of substance, so as materially to injure the form and organization of the part. About the same time, various portions of the skin begin to exhibit the effects of the disease; brown or copper-coloured spots make their appearance, from which a quantity of matter exudes, which concretes into a scurf. This, when it falls off, is succeeded by another scurf, and so on until at length ulceration is established. The next set of symptoms, or the next order of parts that is infected, is the periosteum, and the various appendages of the bones; these become thickened, and at length give rise to painful tumours, called nodes, until the structure of the bones themselves is finally disorganized. There are ceatain bones which seem peculiarly disposed to suffer by the syphilitic poison, especially the small bones of the palate and the nose; and when the disease has got firm hold of the constitution, they are entirely corroded, so as to cause a great defect in the speech, and the most dreadful deformity of the countenance. Along with these symptoms, which are all more or less of a local nature, although depending upon the general diffusion of the poison, the powers of the constitution begin to suffer, the appetite fails, emaciation and loss of strength ensue, hectic supervenes, and the disease terminates fatally. These symptoms are usually recognized as the effects of chancre, and it has been a much disputed point, whether a similar train of complaints can be induced by the poison of gonorrhœa. This we are disposed to decide in the negative; but we do so, as in the former case, in opposition to the judgment of many persons, who are the best able to decide upon the subject. Whatever opinion, however, we may form respecting the contamination of the system by the matter of gonorrhœa, the inflammation with which it is attended has the power of extending itself along the urethra, and the ducts connected with it, thus producing tumours of the neighbouring glands, and especially of the testes. The tumours thus formed, unless the inflammatory action be subdued by proper applications, may proceed to suppuration; but the matter thus generated does not appear to be capable of contaminating the system at large; at least this is the opinion of those who regard the poison of gonorrhœa to be different from that of chancre, or the proper Lues venerea.

This very general outline of the leading features of Syphilis will be sufficient to prove, that many difficulties attach to the pathology of the disease, and we shall find that there is not less obscurity with respect to its treatment. And this does not arise from the same circumstances which we meet with in the management of other diseases, depending upon the obstacles that present themselves to our researches into the operation of medicines on the living body; but here we have to encounter the most direct contradiction of evidence, and we are called upon to decide between the opposing opinions of those who might be supposed to possess the most unexceptionable means of ascertaining the truth. A controversy has subsisted for some time on the question, whether the same general remedies were necessary in gonorrhœa as in chancre, a question which is obviously connected with the controversy respecting the identity of the infection generating the two varieties of the disease. With respect, however, to the proper syphilitic poison, and to its constitutional symptoms, under whatever form they manifested themselves, there was, until very lately, but one opinion, that the only remedy is mercury, the sole question for consideration being, in what way this medicine should be exhibited so as to produce the least injury to the constitution. Every one agreed that mercury possessed a specific power over the venereal poison,—that no other medicine possessed the same power; and so firmly was this opinion established, that it was esteemed a sufficient diagnostic of the presence of the disease, where the symptoms assumed a doubtful aspect, that they yielded to the action of this remedy. But, notwithstanding the supposed invaluable property of mercury as an anti-syphilitic, practitioners were aware that it is a substance which possesses an unfavourable effect upon the system, if used in too large a quantity, and it was admitted that in certain cases, it was a question of extremely difficult solution, whether certain morbid appearances were to be ascribed to the disease itself or to the remedy. Still, however, no one thought of calling in question the indispensable necessity of mercury for the cure of Syphilis; and the injurious effects which it seemed occasionally to produce, were attributed either to some idiosyncrasy in the constitution of the individual, to the injurious administration of the remedy, or to the improper management of the patient while under its influence. A few years ago some practitioners of eminence began to take a different view of the subject; they conceived that there were certain affections, which had always been classed as syphilitic, in consequence of the mode in which they were communicated, and the general aspect of their symptoms, but which were capable of being cured without mercury; from this circumstance they concluded that they must necessarily be of a different nature, and they accordingly termed them pseudo-syphilitic. It then became a point of great importance to form a diagnosis between these cases and those of genuine Syphilis; for not only was the Pseudo-syphilis curable without mercury, but it seemed to be even aggravated by the use of this substance. As the investigation continued to be pursued, opinions arose that were still more remote from those that had been formerly adopted; it was now advanced, that mercury is not essential to the removal of Syphilis itself, and farther, that a considerable part, if not the whole of the constitutional symptoms, are really the effect, not of the disease, but of the deleterious operation of mercury.—We state these points, not as articles of our own faith, for we confess our scepticism upon the subject, but as what have received the sanction of great authorities, and this not of mere theorists, but individuals who have been actively engaged in the details of practice, whose testimony, had it not counteracted all our former experience, and opposed some of the opinions which seemed to stand upon the most incontrovertible evidence, we should have been the most disposed to receive without hesitation It seems that we must regard the public sentiment on this question as now in the progress of a great revolution, the result of which it is impossible to predict; after various oscillations of opinion, we shall perhaps finally settle in a medium state: we shall probably find that there are either different kinds of venereal infection, or that it undergoes certain modifications, which cause it to be differently acted upon by the same remedy, or to require different remedies for its removal.—The general and indiscriminate use of mercury we may safely pronounce to be improper; and when we consider the quantities in which it has been given, with so little regard to peculiarity of constiution, or differences of temperament, we can scarcely doubt that its effects have been almost as injurious as those which would have resulted from the ravages of the disease which it was intended to cure. Yet we should be acting in opposition to the concurring testimony of the whole medical profession for some ages, were we not to allow of the specific effect of mercury over that form of Syphilis which usually presents itself to our notice, so that we may venture to assert, that if we are to give up this point, there is no one position in the practice of medicine which must not be regarded as disputable. For reasons which have been already stated, we shall not enter upon the consideration of the various local forms of the disease; and while such a schism exists respecting the effect of mercury, it would be premature to enter upon any pathological speculations respecting the mode of its operaration. We shall only observe, that, independent of its anti-syphilitic power, its action on the various organs seems to be that of a stimulant, increasing their natural powers, whether of absorption, secretion, or excretion, as well as the vital functions of contractility and sensibility. We know not how this stimulating property can have any influence over the neutralization or expulsion of the syphilitic virus; we see no connexion between the two effects, nor can we conceive of the nature of the relation which they bear to each other.*

---

* On a subject of such importance as that of Venereal complaints, the American editor is induced to offer the following extracts from an Essay on Mercury, by Dr. Francis, the present Professor of Obstetrics in the University of the state of New York. For further observations, the reader is referred to the American Medical and Philosophical Register, vols. iii. and iv. AMER. ED.

"Among the principal advantages which the corrosive sublimate possesses over that of every other preparation of mercury are, that, judiciously administered, it is particularly mild and safe in its operation, will admit of a more extensive use in all the various forms of lues venerea, and subject the patient to fewer inconveniencies: that it readily enters into the general circulation, becomes miscible with the several fluids of the body, the soonest arrests the progress of the complaint, and eliminates the morbid matter through those emunctories best calculated for that purpose: that it supersedes the necessity of salivation, by its action on all the secretions, and by promoting especially the cuticular discharges, and the evacuations from the kidneys: that it is the only preparation to be depended on in those peculiar habits of body, so susceptible to become salivated by every other form of mercury now in use: that, in its ultimate effects upon the constitution, it is attended with comparatively no injury. These facts are indeed truly important, and many of them are granted by those who altogether reject the use of this preparation.

"It is not a little unfortunate for the advocates of other combinations of mercury, that the objections which have been brought against the corrosive sublimate are so dissimilar. It has been assigned as a reason against the preparation itself, that it has failed of its salutary effects by being given in too small doses. By some its anti-venereal properties are said to be lost on account of its too readily exciting the cuticular discharge; by others it is owing to its defective action on the secretions of the skin and mouth. By some it is admitted to be beneficial in the primary stage of the disease, and by others it is contended that it is calculated to remove only secondary symptoms. It is also declared that it is violent and uncertain in its operation, and that it does not render the cure permanent. Some of these objections are, indeed, weighty, and, were they well founded, would fully justify the abandonment of this peculiar combination of mercury; but if the least reliance is to be placed upon the experience and observation of those who have employed the corrosive sublimate with the most disinterested and honourable views, and solely to determine upon its anti-venereal powers, evidence sufficient to prove the fallacy of these objections, and derived from indubitable sources, might be adduced. The testimony of Dr. Locher, of the Vienna hospital, is so full and explicit, that it were an omission not to insert it. Having witnessed the "horrid calamities," arising from salivation and other abuses, which existed in that institution, in the management of venereal patients, upon the recommendation of Van Swieten, he made trial of the corrosive sublimate. From the year 1754 to 1762, he cured by it no less than four thousand eight hundred and eighty persons, *without inducing salivation;* and testifies, that 'no persons died, or experienced the least painful and dangerous symptoms, in consequence of this remedy.' In the cases in which the same preparation was recommended by Pringle, the cures that were effected were permanent, and, from the repeated experience of many other distinguished practitioners, the same result ensued. Multa nobis exempla visa sint luis venereæ, murcurio sublimato corrosivo perfectè sanatæ.

"To enter into a consideration of the treatment of the various symptoms which characterize lues venerea, in its simple and in its more confirmed state, is not deemed necessary, nor will it here be attempted. Fully convinced, as the writer is, of the decided advantages which the corrosive sublimate, as an anti-venereal remedy, possesses, in most cases, over other mercurial preparations, he cannot forbear adding a few further observations, for the purpose of recommending to more general use this combination of mercury.

"A very forcible reason why a preference ought to be given to the corrosive sublimate as an anti-venereal remedy, is the mildness of its operation, when compared with most other mercurial preparations. In the mind of the judicious practitioner, there need exist no apprehensions of the severity of its action; few articles of the materia medica can be more readily accommodated to the peculiar condition of the patient, and the nature and stage of the disease. The evidence of its mildness may be adduced from the salutary effects which it produces in the constitution of delicate children, and even of infants. In not a single instance, within the recollection of Dr. Hosack, has it ever been followed by pernicious consequences, though long employed by him, in many cases in which the patient laboured under some hereditary taint, obstinate cutaneous eruption, or other symptoms indicating an alterative course of remedies. The destructive effects which have been mentioned as attending its administration, such as excessive pain and irritation of the stomach and bowels, headach, fever, &c. may, in certain cases, arise from some peculiarity of constitution obnoxious to mercurial remedies, but are doubtless, in general, to be attributed either to the improper preparation of the corrosive sublimate, or to its having been given in undue quantity. It has been asserted that this mercurial salt is particularly injurious to those labouring under pulmonary affections. That this objection is ideal, or rather that, of all mercurial preparations, it applies with least force against the corrosive sublimate, must be evident, upon considering the general operation of this form of mercury. Every combination of this mineral may prove more or less injurious in the forming stage of consumption, on account of the active inflammation which is then present, and the additional irritation attendant upon mercurial action. For it may be laid down as a general principle, that mercury is in itself injurious, when administered to any considerable extent, during the existence of inflammation and febrile excitement, and before the employment of blood-letting, or other evacuants.

"From the mild operation of the corrosive sublimate, properly prepared, may be inferred the utility of its employment in persons of delicate habit, and in those cases especially where the constitution is materially impaired. In cases of this kind its exhibition is followed with the best effects. That the tonic powers of the system may, however, in certain instances, be so far weakened as to render the employment of every form of mercury not only inefficacious in the removal of syphilitic complaints, but productive of the most distressing symptoms, and, consequently, that the use of the oxygenated muriate will at times be the cause of much inconvenience and real suffering, there is left no room to doubt. In irregular cases of this nature, the remedy necessarily fails of producing its ordinary beneficial effects; and as it becomes an additional source of irritation, it greatly increases the debility which already prevails. These effects, as has just been remarked, do not result from the exclusive employment of any particular form of mercury; they seem

Sect. VIII. *Scorbutus. Sea Scurvy.*

This disease is characterized by general muscular debility, by livid spots on various parts of the body, sponginess of the gums, and hæmorrhage from the alimentary canal. It is one of those diseases in which the soft parts of the body seem to have experienced a morbid change in their physical and chemical composi-

---

to arise less frequently from the corrosive sublimate, but are common to all mercurial preparations. For, if the constitution has not the power to support the action of mercury, vain is the attempt to eliminate from the system the virus of lues venerea. Hence, in the treatment of certain diseases of hot climates, especially in unhealthy situations, it is not an uncommon practice to administer the bark daily, during the whole course, for the purpose of enabling the constitution to bear a sufficient quantity of mercury to subdue the complaint. Upon the same principle, that learned physician and distinguished writer, Dr. Chisholm, maintains, that in the management of disease a reduction of plethora at the commencement, and the augmentation of the vis vitæ in the advancement, are to be particularly attended to, in order to ensure the successful administration of mercury. Dr. Ferriar has observed instances in which the venereal disease itself assumed a peculiar character, owing to debility, where the debility so far prevailed that the constitution had not power to form a genuine syphilis. When this happens, mercury will not effect a cure. 'Under these circumstances,' adds Dr. Ferriar, 'I have advised with success a course of tonics, without mercury, to raise up the constitution to a higher level. Mercury may then be expected to cure.' "

Again, " That the corrosive sublimate, of all mercurial preparations, soonest affects the system, and arrests the action of the venereal virus, is a truth grounded upon the concurring experience of the most distinguished practitioners.

" It is but proper to state, that the preparation of mercury now recommended, has been employed for the last twenty years in the private practice of Doctor Hosack, and during his attendance at the New-York State Prison, New-York Hospital, and the Alms-house of this city, as physician of those institutions. It has invariably been found to be the remedy best calculated for the removal of lues venerea, both in its primary and secondary stages; and not a single case is recollected in which the cure has not been permanent. Those injurious effects upon the stomach and bowels, which are so much apprehended, were avoided by a cautious employment of the medicine, and by a due consideration of the peculiarities in the constitution and state of the patient. From this form of mercury, salivation scarcely ever was induced; and, while under its influence, the employment of the decoct. guaiac. et sarsaparil. was found to be an excellent auxiliary in recent cases; and in the secondary stage of the disease, where the patient had been neglected, or when improprieties in the cure had been committed, it was almost indispensable.

" Though satisfied that the oxymuriate of mercury possessed full claims to the title of a powerful anti-venereal remedy, from a perusal of the testimony published in its favour, and from a personal knowledge of the result of several cases in which it had been employed; with the view of more fully determining so important a matter, and to ascertain, as far as practicable, whether the objections which have been stated against it, particularly those of the distinguished Mr. John Pearson, were founded in reality, at the suggestion of the writer, the use of the corrosive muriate of mercury was adopted in the spring of the year 1811, in the New-York Hospital. From the extensive charity which this excellent institution afforded, there was abundant opportunity of seeing almost every form of this disease, from the more mild to the most aggravated; cases of recent infection, and those of long standing. After a careful examination of the histories of a great variety of cases, a selection was made of several of those patients who were affected with the primary, and of others labouring under the secondary stages of this disease. The corrosive sublimate was given, in some instances, in the form of the spirituous solution, and in other instances made into pills; the decoction of guaiacum and sarsaparilla was employed as an auxiliary, and occasionally recourse was had to the application of the lunar caustic; but the external use of every preparation of mercury was omitted. In no one instance were there unpleasant effects produced by the action of this mercurial salt; and, contrary to the opinion entertained by Mr. Pearson, of the efficacy of this remedy, the result of these several cases was attended with complete success.

" To multiply further arguments, or offer additional proofs in favour of the oxygenated muriate of mercury, does not seem necessary. It may be confidently pronounced a safe, convenient, and efficacious remedy in lues venerea. How far a too ready acquiescence in the force of authority may be assigned as the cause of that want of confidence in the virtues of the corrosive sublimate, and of that apprehension of its pernicious qualities which at present prevails among many practitioners, it is impossible to ascertain. It is evident that the opinions of Mr. Pearson are those chiefly which have been adopted and reiterated by every subsequent writer who has opposed the use of this mercurial combination. But the success attendant upon the administration of the oxymuriate of mercury furnishes the most satisfactory answer that can be given to those who have denied its efficacy. Upon the successful result of the cases of lues venerea, which existed in the New-York Hospital in 1811, the corrosive sublimate again became the principal anti-venereal remedy in that extensive establishment. This form of mercury, since that period, has also been in general use in the New-York Alms-house, in the treatment of syphilis in its different stages; and in most instances it is now employed for the same purpose by the physicians of the City Dispensary. The observation and experience of the writer, during the last three years, in a number of unequivocal cases of lues venerea, have tended to corroborate the favourable opinion he formerly expressed, and induce him to recommend, with increased confidence, a more extended application of this preparation of mercury.

" Various are the forms in which the corrosive sublimate has been used in the different stages of lues venerea, and in other disorders indicating an alterative course of remedies. Its external application, in the form of ointment, has been recommended by some; but against this practice many forcible objections might be brought. The internal use of the spirituous solution of Turner, in which the proportion of ardent spirits to the mercurial salt was remarkably small, has justly been accused as the source of much mischief. The formula of Van Swieten deserves a decided preference; for the muriated quicksilver, dissolved in spirits, and exhibited in doses limited to the quantity of one-eighth of a grain, two, or, at most, three times in twenty-four hours, seldom produces the least nausea, or any derangement of the stomach or bowels.

" The corrosive sublimate, dissolved in common brandy, in the proportion of two grains of the salt to one ounce of the liquid, is a valuable and convenient preparation for delicate children. It may be given with the greatest safety, in a little sweetened water, to the amount of three or four drops to a child of one year, and repeated three times a day; and to a child of two or three years old, six or eight drops three times a day. After its employment two or three days, the dose may be increased to ten or twelve drops.

" A solution of the oxymuriate of mercury in common distilled water, with the addition of a little muriated ammonia, (sal ammoniac,) is also a judicious and safe pharmaceutical combination.

" But the best form of administering the corrosive sublimate is that in which this mercurial salt, united by solution with the muriate of ammonia, is made into a mass with the crumb of wheat bread, and then divided into pills.

℞. Oxymuriat. Hydrarg.
Muriat. Ammon. aa gr. xv.
Aq. distillat. vel. font. ℥ ss. Solutioni addatur
Panis medul. sic. q. s.
Ut fiat massa, in pil. cxx. dividenda.

" Every pill in this prescription contains, if the materials be uniformly combined, the eighth of a grain of the corrosive sublimate. The dose can, therefore, easily be regulated with the greatest accuracy. Of these pills one is to be taken every night and morning, though, in some aggravated cases, another pill may be taken at the middle of the day, with additional advantage. In this manner a quarter of a grain of this preparation of mercury will, in ordinary cases, be taken in twenty-four hours; and in the more severe form tion; for not only do we find a depravation of all the functions, but, if we except the bones, there appears to be an alteration in the nature of all its constituents, both solid and fluid. The exciting causes of Scurvy are ascertained to be all those circumstances which deprive the body of its due quantity of nutrition, or weaken the action of the digestive organs, and prevent them from completing the office of chylification, such as exercise and fresh air; and upon the same principle we find, that whatever depresses the spirits has a powerful influence in aggravating scorbutic affections. As its name imports, it generally makes its appearance among sailors during long voyages, when they have been for a long time without a supply of fresh provisions; but precisely the same symptoms have made their appearance among the inhabitants of beseiged towns, or among armies who were exposed to the same deficiency of fresh food; and from a similar cause Scurvy is generally endemic in Greenland, and the other northern countries, where the inhabitants are necesssarily deprived, during the greater part of the year, of all vegetable food. The proximate cause of Scurvy, or the way in which the exciting causes induce the symptoms, has been the subject of much speculation, and has given rise to many pathological hypotheses, all of which, however, we apprehend will prove to be without foundation. The symptoms which arise from the mere privation of food, do not correspond to those which form the leading features of Scurvy, nor do we know in what way the peculiar condition of the soft parts which constitutes this disease can proceed from the use of salted provisions, of impure water, or of a putrid state of the substances received into the stomach. With respect to the theories which ascribe Scurvy to some chemical change in the blood, such as a defect of oxygen, they may be considered as altogether unfounded, and resting entirely upon the most fanciful analogies; and although the old hypothesis, which conceived the fluids to be in a putrid state, is deficient in evidence, still it appears to be less inconsistent with the acknowledged phenomena. We must therefore consider this to be one of those points of medical theory which are not yet ascertained, and not, as far as we can judge, referable to any general principles. Fortunately, however, the want of a correct theory has not prevented us from acquiring an effectual manner of treating the disease, for we may consider Scurvy as one of the few complaints for which we possess a certain specific, which in all cases removes the disease, provided no circumstance intervenes to counteract its effects. This remedy is the citric acid, which effectually cures Scurvy almost in its worst form, provided only that we have it in our power at the same time to remove the exciting causes. We find indeed, that when we are able to afford the patient a proper supply of fresh vegetable food, the symptoms will generally yield without the use of the citric acid, although this will, in all cases, contribute to expedite the cure. It does not appear that any other acid possesses the same power in

---

of lues venerea, the additional eighth of a grain. Instances may occur, in which it may be advisable to administer half a grain daily. Mr. Bell has given a grain of the corrosive sublimate, divided into four or five doses, but has not been able to continue this quantity for more than two or three days together.

"The corrosive sublimate to the amount of one quarter of a grain a day, and, in some cases, an additional eighth of a grain, in pills, may be continued for a long time, without producing the least inconvenience in the stomach and bowels, and with greater certainty and more beneficial effect than the same quantity of this salt, in the form of the spirituous solution. The use of the corrosive sublimate ought to be continued two or three weeks after the disappearance of the disease, in order more effectually to accomplish a radical cure.

"It has already been observed, that the oxygenated muriate of mercury operates more readily on the constitution than any other form of this mineral, and that even in very small quantity it soonest arrests the progress of venereal symptoms, and, by its general action, eliminates the poison of the disease. It deserves to be stated, that during the use of this preparation, all those precautionary measures, with regard to diet and regimen, which are generally recommended by writers, need not be regarded with the same scrupulous attention, while in the use of the corrosive sublimate, as during the employment of other mercurial medicines. For as the corrosive sublimate rarely affects, to any considerable degree, the salivary glands, those subjected to its use are not rendered so susceptible to the influence of cold, and the physician is seldom under the necessity of devising means for the purpose of obviating the pernicious consequences of salivation. Instances of peculiarity of constitution may occur, which require much management and discretion in the use of this remedy. Mr. Bell has observed, that opiates have not the same influence in preventing an undue action of the oxymuriate of mercury upon the stomach and intestinal canal, which they commonly have with other mercurial preparations. The limited experience of the writer has not in any case corroborated this opinion: on the contrary, he has found an occasional recourse to small quantities of opium highly serviceable.

"As some one or more articles of the vegetable kingdom are in general employed in those cases, in which the corrosive sublimate is administered, it perhaps would not be irrelevant to examine how far they are entitled to particular confidence. It may be proper to remark, that of the many substances which have been employed as auxiliary remedies, or are now in use, the *lignum guaiaci* and the *radix sarsaparillæ* unquestionably claim the first notice. They are acknowledged to be useful during the administration of the oxymuriate of mercury, in cases of recent affection; and, in the secondary symptoms of the disease, for the removal of the evils which have taken place from the injudicious employment of mercury, &c. their salutary operation has been uniformly evinced.

"The compound decoction of guaiacum and sarsaparilla may readily be prepared in the following manner:

℞. Rasur. ligni guaiac.
Rad. sarsapar. fissæ aa. ℥i.
Coq. in aq. font. ℔iij. ad ℔ij.

"Of this decoction the above quantity, taken warm, ought to be drunk within the twenty-four hours. Of its effects as a powerful alterative for the removal of some of the most painful symptoms of lues venerea and obstinate cutaneous affections, indubitable evidence exists in the pages of the old, and in those of the most eminent modern authors. During a period of more than forty-five years, its virtues for these purposes have been tested in the practice of that learned and distinguished physician, Dr. Samuel Bard, and for more than twenty years in the practice of Dr. David Hosack. Its salutary properties appear to be owing chiefly to the general excitement which it produces, and to its action as a diaphoretic. When had recourse to, while in the use of mercury, particularly in the treatment of those cases where the disease is of long continuance, it proves eminently useful, by promoting the natural tendency which the corrosive sublimate possesses to increase the cuticular discharge.

"The compound decoction of the guaiacum may be taken with success for the removal of many of the morbid effects produced by the improper employment of the different preparations of mercury, and for restoring the constitution to its wonted vigour. The advantages arising from the use of the *Rob Anti-syphilitique,* for which so enormous a consideration is demanded, may with confidence be attributed principally to the sarsaparilla which enters into its composition."

Scurvy with the citric, except so far as they may contribute, in certain states of the digestive organs, to aid in the process of chylification.

We may remark, in connexion with this subject, that no department of the medical profession has conferred more benefit upon mankind than that which respects the health of seamen. To so great a degree of perfection are we arrived in every part of the naval police, with respect to food, clothing, and discipline, both moral and medical, that scurvy is now become a comparatively rare occurrence; the longest voyages are accomplished with little risk of disease, and even with less injury to the health, than what usually happens to the same number of men placed under the ordinary circumstances of civil life.

Sect. IX. *Hydrops. Dropsy.*

The third order of the Paratrepses consists of the Hydropes, a set of diseases which appear to originate from an affection of the minute vessels belonging to the serous membranes that line the close cavities of the body. These vessels, in their natural state, secrete a serous fluid, which is taken up by the absorbents as rapidly as it is discharged; but in certain conditions of the system these two operations do not proceed in exact proportion to each other, in consequence of which an accumulation of fluid ensues, which produces the diseases in question. This accumulation may take place in the cellular texture, which pervades all parts of the body, essentially consisting of a series of small cells, that are furnished each of them with the appropriate apparatus for secretion and absorption.

This species of Dropsy has obtained the name of Anasarca, and, according to circumstances, it either extends through the whole of the cellular texture, or occupies certain portions of it only. The exciting causes of Anasarca, as well as of Dropsy in general, are various, and not well ascertained; it is a frequent sequel of other diseases, by which the vital powers in general, and especially the contractility of the muscular fibre, appear to be weakened; it is also induced by other debilitating causes, as excessive evacuations, want of proper nutrition, over fatigue or exhaustion. There is also another set of exciting causes, which appear to be more of a mechanical nature, and which may be all referable to a physical obstruction of the absorbent vessels; and there is a third set of exciting causes of dropsy, which are not strictly to be included in either of the preceding classes, viz. various circumstances which impede the digestive functions, especially structural diseases of the different abdominal viscera. In some cases indeed these affections may be attributed to the pressure of the parts, when they become indurated, upon the thoracic duct or the trunks of the absorbents, but in other cases it would seem to proceed from a constitutional cause; the Dropsies that are produced in this way are principally those of the cavity of the abdomen, to which the term Ascites has been applied. There appears to be in some individuals, what may be called a Dropsical Diathesis, where serous effusion, in one or more parts of the body, is liable to take place from very slight causes, or perhaps without any assignable cause whatever.

The proximate cause of Dropsy must obviously consist either in increased secretion or in diminished absorption of the serous fluid, unless we suppose that these two states can exist at the same time; we have, however, considerable difficulty in deciding to which of the two causes each individual case should be referred, or to determine in what manner some of the exciting causes can operate. As they are in most cases debilitating, we might conclude that the deficiency of absorption was a more frequent occurrence than the excess of secretion; and the treatment which is found most successful in Dropsy; may probably seem to countenance this idea, yet it must be acknowledged that the pathology of the disease is altogether obscure, and that we have no direct facts to guide us in our decision. One of the most remarkable symptoms in Dropsy is the change which is effected in the state of the urine; it is much diminished in quantity, and is altered in its quality; the proportion of the watery part to the solid contents being considerably reduced, so as to render it thick and high coloured, and to cause it to deposit, as it cools, a copious sediment. In some cases of Dropsy the urine has been found to coagulate by the application of heat, proving that it contains a portion of albumen; and as the presence of albumen has been conceived to indicate a different condition of the system from that which prevails in the more ordinary kinds of Dropsies, considerable importance has been attached to this circumstance, both in a pathological and a practical point of view.

In attempting to cure Dropsy we are first to inquire whether the disease be primary or symptomatic; and if we conclude it to be only symptomatic, we are of course to apply our remedies to the removal of the original disease. But when this cannot be accomplished, or when we are not able to detect any primary affection, we must direct our attention to the Dropsy itself; and the two obvious indications will be, to remove the effused fluid and to prevent its re-accumulation. The effused fluid may be removed by puncturing the cavities which contain it, and thus mechanically discharging it; but this seldom affords more than mere temporary relief, as, while the same constitutional disposition remains, the water again rapidly accumulates, and it sometimes even appears that it is effused in larger quantity than before, and that the general health is injured by the operation. It must also be remarked, that dangerous consequences occasionally ensue from the punctures, which, however carefully made, are disposed to assume the gangrenous state, from the feeble condition of the vital powers. We must therefore attempt to remove the effused fluid through the intervention of internal remedies, and of these the most effectual are such as produce an increased action of some of the excretory organs, especially the intestinal canal and the kidney. In consequence of that intimate connexion which subsists between all parts of the system, we find that if by any means we produce an increased discharge from one organ, all the rest seem to be excited in the same manner. What is the exact nature of this connexion we are scarcely able to ascertain, but we are acquainted with the effect, and we have frequent opportunities of employing it with advantage in the cure of disease. We have stated that purgatives and diuretics are the two classes of medicines which are usually had recourse to for removing collections of serous fluids, when effused into any of the cavities of the body; and it is accordingly to these substances, and especially to the latter, that we generally look for the cure of Dropsies of all descriptions. When we are able to produce the desired effect upon the kidney, we indeed seldom fail in accomplishing our purpose, but it unfortunately happens that there is no class of medicines that is so uncertain and apparently so capricious in their operation as diuretics. The number of articles that have been employed for this purpose is very considerable, and they are so very different in their nature and sensible properties, that we can scarcely conceive them to act upon the same principle, or even to produce the same effect upon the body. Many of them indeed, it may be concluded, are entirely inert, and have acquired their reputation, solely from some accidental circumstance; but there are others of obvious activity, although even of these it is not easy to say in what manner they act, or how substances of such different qualities can all conduce to the same end. The medicines that are esteemed the most efficacious diuretics are squills, digitalis, cream of tartar, and certain preparations of mercury. Of these the squill is the one which is the most certain in its effects, and which seems to be applicable to the greatest variety of cases, so that unless there be some peculiarity in the constitution, which prevents us from administering the medicine in proper quantity, or some structural disease which counteracts its operation, it seldom fails in increasing the flow of urine. The varieties of Dropsy in which the squill is thought to be the most useful are Aanasarca and Ascites. Digitalis is a medicine which possesses great power over the system, but which, although occasionally very beneficial, manifests its deleterious effects, and becomes decidedly injurious, if it be employed improperly or in excessive quantity. When we consider the nature of the primary action of squills and digitalis, we can scarcely suppose that they operate upon the same principle, yet as we are not able with any degree of precision to explain the nature of their operation, we are decided almost entirely by mere experience, in determining upon the individual cases for which they are each of them more peculiarly adapted. The variety of Dropsy called Hydrothorax, in which the cavity of the chest is the seat of the disease, has been generally conceived to be the one in which digitalis is most serviceable; and it is agreed that a languid, or, as it is metaphorically termed, a relaxed habit and a phlegmatic temperament, is better adapted for the exhibition of this medicine than a constitution of an opposite description. The supertartrate of potash has been spoken of by many respectable practitioners as a powerful diuretic; and there are other neutral salts, principally those into the composition of which the tartaric and acetic acids enter, which are generally supposed to possess the effect of promoting the action of the kidney, but they are all of uncertain operation. When they prove successful in increasing the quantity of the urine, they commonly, at the same time, act as purgatives; and it may be questioned whether they are to be considered as any thing more than mild hydragogues, the peculiar property of which is, to cause a copious watery discharge from the mucous surface of the intestines, in which the urinary organs may also partake. We have sufficient evidence of the effect of mercury as a diuretic, but it may probably be referred with more propriety to its operation as a general stimulant, than to any specific action upon the kidney: and this opinion appears to be countenanced by the fact, that the use of mercury in Dropsy is principally as an adjuvant to other substances, for example to squills and digitalis. If the hypothesis be not too mechanical, we may regard mercury as a stimulant to all the secretory organs, probably in proportion to their degree of vitality, or their connexion with the circulating system; but that its operation may be more particularly directed to any one of them, by being united with a medicine which acts specifically upon the part; of this we have an illustration in what we observe with respect to purgatives as well as diuretics. Perhaps the only cases in which we can consider mercury as having any direct effect in the removal of Dropsy, is where the disease depends upon the enlargement of some glandular part, either by the constitutional derangement as connected with the digestive organs, or merely by its mechanical pressure upon the great trunks of the absorbents; the power which mercury is conceived to possess in discussing glandular tumours, being independent of its action on the kidney. As to the second indication in the cure of Dropsy, to prevent the re-accumulation of the fluid after it has been removed, all that can be said on this point may be included in the single direction of adopting every means for improving the general health, we must avoid the exciting causes, and we must endeavour to strengthen the digestive organs by temperance, exercise, preserving an open state of the bowels, and by the proper exhibition of tonics.

After these general remarks on Dropsies, as constituting an order of diseases, we must proceed to make a few observations upon the different genera. Concerning Anasarca we have little to add to what has been said above, either as to its symptoms or its cure; for as it is the most universal in its seat, so it presents us with the fewest peculiarities with respect either to its symptoms or its treatment. Purgatives, exhibited according to the strength and constitution of the patient, of which the neutral salts and the hydragogues will probably be found the most appropriate, are sometimes alone able to effect the removal of the effusion. If these fail, we proceed to diuretics, of which squills, in combination with calomel, suggest themselves as the first to be tried. Along with these, or rather to complete the cure after they have accomplished their object, we must have recourse to the same kind of tonic treatment which is employed in other diseases, where the strength has been much reduced.

Ascites is a more formidable disease than Anasarca, as it generally depends upon a structural affection of some of the abdominal viscera, or upon a local derangement, which is out of the reach of medicine, or is connected with some other morbid condition of the system. The disease is characterized by distention of the abdomen, in which the fluctuation of a fluid may be distinctly perceived, and to this local symptom, which properly constitutes the disease, we have always considerable disturbance of the system generally, loss of appetite, and torpor of all the organs concerned in the function of digestion; the usual deficiency of urine occurs, and as the disease advances, the strength fails, the flesh wastes, and ultimately hectic, with complete atrophy, supervenes. Besides other causes of uneasiness, the patient suffers great distress from the mere bulk of the abdomen, which is often so large as materially to interfere with the various vital and organic functions, especially the respiration and the circulation. The fluid is usually effused in the general cavity of the peritoneum, but in some cases it is contained in a partial cyst; in these instances the constitutional symptoms are generally less urgent, as the affection may be supposed to proceed from some cause of a more local nature, which, at its commencement, has but little effect upon the system at large. It is indeed principally from the proportion which the general bears to the local symptoms, that we are to form our judgment respecting the seat of the effused fluid, whether it be encysted or not, a fact of some consequence in the treatment of the disease, and one of very great importance in its prognosis.

In treating Ascites, the only point to be considered, in addition to the general principles which we have laid down above, respects the propriety of discharging the water by an operation. Where the tumour is very large, and where it seems, by its mechanical bulk, to injure the action of any of the functions that are essential to life, we occasionally find it necessary to puncture the sac, but, for the most part, we derive little permanent benefit, and it would appear that we not unfrequently bring the disease more rapidly to a fatal termination. Ascites, when it proceeds from a structural disease of any of the abdominal viscera, which is one of its most frequent causes, can only be effectually treated by the employment of those remedies which act upon the diseased organ; and it must be confessed that, in these cases, our prospect of success is very limited. A cautious use of mercury, in combination with squills, is perhaps the best remedy that can be tried; but it will be often found ineffectual, and a variety of occurrences almost daily present themselves, which will demand our attention, and oblige us to swerve from any regular plan of treatment which we may wish to adopt.

Hydrothorax, or Dropsy of the chest, is characterized by difficulty of breathing, which is increased in the horizontal posture, by disturbed sleep, palpitation of the heart, irregularity of the pulse, and frequently by all the symptoms of general Dropsy. Sometimes, by certain motions of the body, or by certain postures, the presence of the fluid in the chest may be perceived by the patient himself, and it may be felt by the practitioner, when he employs a peculiar method of striking the chest, or pressing upon the contiguous parts. The immediate cause of Hydrothorax, like that of Ascites, is generally a disease of some of the viscera; and as, from its local situation, it is more connected with the functions which are essential to life, its prognosis is more unfavourable. It has been generally supposed that this species of Dropsy is more peculiarly adapted for the administration of digitalis than any other remedy; a circumstance which, if correct, may perhaps be explained by the power which this remedy possesses over the circulation. When we determine to prescribe this substance, it should always be done with the greatest caution; and if we do not find it to be useful after it has been taken for a short time, we are not to expect any benefit from the farther continuance of it; for were we to persevere, we should probably experience its deleterious effects. Purgatives are always indicated in Hydrothorax, and the operation of the various neutral salts, as being the least stimulating, and at the same time possessing the hydragogue property, we conceive to be the most appropriate. It may be doubted whether blisters or other remedies applied externally to the chest can be of any avail in this complaint; and with respect to the operation for discharging the fluid by an artificial opening, besides the objections that were urged against the analogous practice in Ascites, we have here the additional objection, that it is more difficult and painful, that it is less easy to ascertain the unequivocal existence of water in the chest, and that the subjects of Hydrothorax are more frequently persons advanced in life, of a bad habit of body, or debilitated by other diseases, and therefore less likely to derive any benefit from the discharge of the fluid, than many of the subjects of Ascites, so that, upon the whole, we should conceive, that it can only be under a very rare combination of circumstances that this operation should ever be recommended.

With respect to the other kinds of Dropsy, we have already given an account of Hydrocephalus among the diseases affecting the head; for although it may be correctly placed among the Hydropes in a nosological system, yet, in a pathological and practical point of view, it more properly comes under the Neuroses. The Hydrops pericardii is a disease, the existence of which it is difficult to ascertain before death, and for which we have no appropriate remedies, while the other genera that have been enumerated, so far as their treatment is concerned, fall under the province rather of the surgeon than of the physician.*

---

* Dropsy is still a disease of frequent occurrence and lamentable fatality: the theories concerning its causes and nature have been as various and conjectural as the means proposed for its removal. Hence the most dissimilar articles of the materia medica have at different times been recommended as certain remedies for the cure of this disease, in its various forms. It seems consonant with our best views of the animal economy, both in health and in disease, to consider Dropsy, in a great majority of instances, as the result of an increased secretion of the serous fluid; and, in attempting its removal, due regard ought also to be paid to its character as a symptomatic, or as an original affection. In the text are enumerated the diuretics generally esteemed the most efficacious in the different varieties of dropsy; and of these remedies the scilla maritima, especially when united with mercury, claims a decided preference. It may be questioned whether, even in Hydrothorax, the digitalis can be administered for any length of time with advantage: in the other forms of Dropsy, experience warrants the conclusion that it has been the occasion of much mischief. When Dropsy is the result of plethora, and depends upon an increased exhalation, the lancet appears to be one of our most available resources, and, in this state of the system, the digitalis, administered temporally, may be of some advantage; but in the second stage of this disorder, when symptoms of fulness or of preternatural excitement do not exist, the use of the foxglove not only adds to the debility of the patient, but evidently aggravates the complaint. The theory of the curative action of mercury in Dropsy, stated above, is on the whole the most satisfactory. The elaterium might, with much propriety, have been mentioned among the number of the most powerful remedies in Dropsy. The late Dr. Ferriar has successfully shown, that it surpasses every other medicine in its power of removing serous accumulations, and in relieving dyspnœa arising from hydrothorax and ascites. He has briefly related the particulars of twenty cases, in which the elaterium was prescribed with various success.

"The sensible effects of the elaterium," says Dr. F "are severe and constant nausea, frequent watery stools, and, in considerable doses, vomiting It does not uniformly increase the urine, and for this reason it is generally proper to combine it with more certain diuretics. After continuing the use of the medicine for some days, the patient will sometimes bear a considerable increase of the dose. I have gone to the extent of five or six grains a day, in this manner, without producing any inconvenience. But it is always proper to begin with the lowest dose, which is the sixteenth part of a grain of the extract." Med. Hist. and Reflect. vol iv.

The writer of this note, from the observation and experience of several years, is convinced that the elaterium is entitled to the

Sect. X. *Cutaneous Diseases.*

We have made the various diseases of the skin the fourth order of the Paratrepses, an arrangement which we are induced to adopt, because we regard them as, for the most part, proceeding from, or depending upon, a morbid condition of the body, connected with a defect of some of the functions either directly or indirectly concerned in the process of nutrition. Some of them are, no doubt, entirely local in their origin, and remain so during the whole of their progress; but in the general view which we are now taking of the subject, it would not be practicable to attend to these minute distinctions, nor indeed is the limit between those that are strictly local, and such as exercise a more general operation over the body, drawn with that exactness, as to enable us, even with every degree of attention, to determine to which class many of the individuals may belong. In a nosological system, which is exclusively appropriated to the consideration of cutaneous affections, it is necessary to introduce every complaint of the skin, although it may appear to be only one symptom, and that perhaps the least important of a number of others that constitute the disease; but in a more general arrangement, we place many of the eruptions, as Small-pox, among the Exanthemata, or in other classes, according to the nature of the circumstance that gives their distinguishing character. In a practical point of view, the most perfect arrangement of cutaneous diseases would be derived, not so much from their visible form, whether they presented the appearance of pimples, vesicles, ulcers, &c. as from a combination of those circumstances which might throw light upon their seat, or their proximate cause. We are, however, altogether unable to accomplish this, except in a few instances, and therefore we must have recourse to a more technical method of classing them according to their external characters. The most scientific arrangement upon this principle, is that in which the cutaneous affections are distributed into eight genera, according as they essentially consist in pimples, scales, rashes, blebs, pustules, vesicles, tubercles, or spots. It would be obviously inconsistent with the nature and object of this work, to enter into a minute examination of all the various modifications which these diseases assume, or even to describe them individually in their more ordinary forms. Indeed, the management of them may almost be considered as a separate department of the art, like that of surgery, and as not falling under the cognizance of a general treatise on the practice of medicine. We shall, therefore, aim at nothing more than to offer a very few remarks, relative to the general principles upon which we treat these complaints, without descending to a separate enumeration of them.

In the first place, exclusive of those cutaneous diseases which essentially consist in Fever, and of which the eruption is only an accompanying symptom, such as Small-pox and Measles, we may consider them as belonging to the two great divisions of acute and chronic, or, what amounts nearly to the same thing, of such as are constitutional, and such as are local. The first of them come on suddenly, and produce some disturbance of the functions, and after running through a regular course, manifest a tendency to a spontaneous cure; the second come on gradually, continue for an indefinite length of time, disappear, and again make their appearance in an irregular manner, and this without necessarily producing any constitutional action, or being accompanied by any change in the state of the functions. A second important circumstance respecting cutaneous diseases is, whether they are contagious or not; the greatest part of them are certainly not so, but there are others which exhibit this property in the most marked manner, and which it is therefore necessary for us to guard against in our management of such cases. In the 3d place, some cutaneous diseases are obviously hereditary, the children of those who have been affected by them having a peculiar tendency to such affections. In the 4th place, different cutaneous diseases are observed to attach themselves especially to different periods of life, some being confined to childhood, others appearing more commonly about the period of puberty, and others again in old age. In the 5th place, the habits of life, especially with repect to exercise and temperance, the nature of the employment, local situation and climate, and many other circumstances, both external and internal, have a very powerful influence in the production of cutaneous diseases; and the same may be observed with respect to the state of society, and the degree of civilization, which, except in a few instances, where there has been too much indulgence in the luxurious gratifications of the palate, tends most materially to diminish the violence, or even altogether to annihilate some of the most loathsome of them. Independent of all these circumstances, there are causes which we are quite unable to comprehend, from the operation of which certain affections of the skin prevail at certain periods, and afterwards become nearly extinct, in this respect resembling various other classes of diseases, in which these alternations of increase and decline are not unfrequently observed, and which are equally difficult to refer to any assignable cause.

In the cure of cutaneous diseases, the first point to be attended to is, how far we are to employ general remedies, or how far we are to rest satisfied with mere topical applications. Probably, in a great majority of instances, they will both of them be necessary. There are, indeed, some of these affections which may be cured solely by topical remedies, while, on the contrary, there are others which require only constitutional treatment. The general remedies may be classed under the heads of those that tend to diminish febrile excitement, of purgatives, sudorifics, and tonics, to which we must add specifics, those which cure the disease without producing any sensible effect, which we can refer to a gene-

praises bestowed upon it by Dr. Feriar: it is a powerful and certain hydragogue, doubtless to be administered with caution. It may, with safety, be prescribed to the extent recommended in the preceding extract. A judicious and prudent course seems to be, to commence its use with the third of a grain, three or four times a day, and never exceeding two grains, three times a day. It may be united with small doses of cream of tartar or of calomel. In cases of extreme torpor of the intestinal canal, where the ordinary remedies have failed of their wonted effects, the writer has witnessed the complete success of the elaterium It is somewhat remarkable, that the able author of the text should have taken so singular a pathological view of Hydrocephalus, as to class it among the Neuroses.

Francis.

ral principle. In applying these remedies, we must obviously select them according to the supposed necessity of the case. We inquire whether there be any febrile excitement, any torpor of the bowels, dryness of the skin, defect of appetite, or general weakness, and we then use the appropriate remedies. The local remedies for cutaneous affections may be arranged under the heads of stimulants and sedatives, those which excite or diminish the action of the vessels of the skin; emollients, those which mechanically soften or relax the parts; and here also, as in the former case, we must introduce a class of specifics. Of the existence of a class of remedies, which have the power of stimulating the skin when applied to its surface, we have sufficient evidence; but there is considerably more difficulty in clearly distinguishing the action of sedatives; and when we wish to produce this effect, it is generally accomplished in an indirect manner, or simply by the removal of some stimulating cause. The circumstances which direct our judgment in the choice of remedies, are derived partly from inquiring whether the symptoms indicate an excess or a defect of action in the part, and partly by tracing an analogy between the disease under consideration, and others, with the treatment of which we are better acquainted,—a kind of practice, it must be confessed, which is often very empirical, and the result of which is very uncertain. Of this uncertainty we have the most convincing evidence in the writings of those, whose judgment and information on these topics is held in the highest estimation; for we find that they proceed principally upon the experience that is derived from insulated facts, and that they frequently recommend, for the cure of the same disease, remedies that appear to be of the most opposite nature, in the selection of which we have very little explicit direction, but are recommended to try them in succession, and to adhere to that which appears to be the most beneficial. Upon the whole, we may conclude, that whatever promotes the general health must be always favourable to the relief of these diseases, and in many cases will effect a cure; that, for this purpose, it is of the highest importance to obtain a healthy state of the digestive functions, and that temperance, fresh air, exercise, and purgatives, are to be regarded as the basis on which we are to proceed, and which will materially assist us in the future progress of the cure. Upon this principle, we shall be at no loss to account for the benefit that is obtained from purgative saline waters, and when they contain sulphur, which has a decided claim to be considered as a specific in certain cutaneous diseases, they present us with the most effectual remedy for some of these affections. Calomel has been very generally employed in these cases, and there can be no doubt of its frequently proving highly useful; but we should be disposed to refer its good effects to its action as a purgative, or at least to the power which it exercises over the organs that are concerned in the processes of digestion and assimilation. We have but little confidence in most of the boasted specifics for cutaneous diseases; they are generally given after the exhibition of more active remedies, if not in conjunction with them. Their operation, even as admitted by their advocates, is slow, and unattended with any sensible effects, and they are commonly prescribed in connexion with some system of regimen, or with some change in the occupation or mode of life, to which we may, with more probability, refer any advantage that is gained. We must, however, make an exception in favour of sulphur, of the efficacy of which no one can doubt, and the same remark may be also extended to arsenic, and probably to iron, but of the nature of their operation we do not presume to offer any opinion. As to the whole tribe of stimulants, both the various chemical preparations, acids, alkalies, metallic oxides, and salts, as well as the acid vegetable substances, we have little to observe in the way of general principles, how far any of them ought to be regarded as possessing specific virtues, or whether they differ from each other solely in the degree of their stimulating power, or in their mechanical properties, we do not feel competent to decide.

CHAP. V.

Pareccrises.

Sect. I. *Diarrhœa.*

We have placed the diseases of the secretory organs in a separate class, under the title of Pareccrises, and have divided them into the two orders of Apocenoses and Epischeses, according as they produce an excess or a defect in the quantity of the secreted fluid. In the first order we have the following genera, depending upon the organs which they immediately affect, Diarrhœa, Cholera, Hyperuresis, Blennorrhœa vesicæ, Lithiasis, Menorrhagia, Leucorrhœa, Ptyalismus, Ephidrosis. These diseases may be considered as, in a great measure, local in their origin, and during their progress are not essentially productive of any constitutional disturbance; they are not necessarily attended with fever, they have no effect upon the nervous system, except upon those parts of it with which they are in immediate contact, and they may frequently be removed by remedies that seem to act locally, or without the intervention of any organ besides that to which they are directly applied.

The first genus of this order is Diarrhœa, a very common disease, which consists in an increased discharge from the alimentary canal, the evacuations being but little affected, except in their assuming a more liquid consistence; they are generally preceded or accompanied by flatulence and a griping pain in the bowels, and frequently by sickness; but this should perhaps rather be attributed to the same cause which produces the Diarrhœa, than be considered as a part of the disease itself. The symptoms of this complaint are so obvious as seldom to leave any doubt respecting its existence; but there are two diseases that resemble it, and from which it is important to distinguish it, Dysentery and Cholera. For the most part an attention to the nature of the evacuations is sufficient to point out the distinction, or if, as occasionally happens, the diseases appear to run into each other, our remedies must be administered accordingly, always adapting them rather to the symptoms than to a technical nomenclature. The exciting causes of Diarrhœa are various; perhaps the most frequent is repletion of the stomach, or the reception into it of some kind of indigestible food; cold applied to the surface of the body, and especially to the legs and feet, is also an exciting cause of Diarrhœa; and it is occasionally produced by impressions upon the nervous system, or even by mere mental emotions. In children, the peculiar irritation produced by teething seems to be a frequent exciting cause of Diarrhœa, as well as that which arises from the presence of worms in the alimentary canal. Although the evacuations in Diarrhœa essentially consist of fæculent matter, they vary considerably in their appearance; and from observing these variations, we have it in our power, in some cases, to judge of the state of the parts which immediately give rise to it. Diarrhœa is often symptomatic of some other disease, many instances of which have been stated above; of these, one of the most violent is the colliquative discharge from the bowels which occurs in the latter stages of hectic fever. It is also a frequent attendant or sequel of the affections of the liver that come on after a residence in hot climates, and is then found to be one of the most unmanageable symptoms of these diseases.

In its simple form Diarrhœa is not difficult of cure, and, perhaps, in a great majority of cases, would be relieved by the mere efforts of nature, as it is a complaint for which a direct remedy is provided in the constitution of the living body, so as to afford one of the strongest arguments in favour of the doctrine, which was once so generally adopted, that all diseases are salutary efforts of the system, expressly intended to ward off some greater danger, which they effect without the intervention of art. In most cases, however, the aid of medicine may be advantageously had recourse to, either to mitigate the violence of the disease, or to prevent it from degenerating into some affection of a more injurious tendency. The obvious indications are, first to remove the exciting cause, if it still remains applied; and, 2dly, to obviate that state of the system which is induced by the immediate action of the complaint.

The proximate cause of Diarrhœa appears to be an increase of the peristaltic motion of the intestines, which may depend either upon a stimulating substance applied to them, or upon an increased sensibility in the part, rendering it more easily affected by the ordinary stimuli. When the disease depends upon the first of these causes, there can be no doubt of the method to be followed in the cure; and as cases of this description constitute a great majority of those that fall under our observation, we shall generally find it necessary to direct our chief attention to this object. For this purpose we shall find the most effectual remedies to be mild purgatives, given in small doses, and frequently repeated, by which the offending matter is discharged more effectually, and with less pain and distress to the system, than if left to act upon the part without assistance. Along with the purgatives large quantities of mild diluents will be found serviceable; and the food should be of the least stimulating kind, and be composed as much as possible of liquids. The choice of the purgative will depend upon the state of the stomach, and various other circumstances; neutral salts, castor oil, rhubarb, and magnesia, are perhaps among those that are the most generally applicable; the last will be especially proper when we have reason to suspect an acid state of the alimentary canal. After the due exhibition of purgatives, we shall generally find the complaint to subside without the use of any other remedies; and, by a proper regulation of the diet, the parts resume their healthy action. Occasionally, however, the Diarrhœa continues after all the offending matter seems to be removed, and the digestive process remains much impaired, while the patient is, at the same time, harassed with griping pains and flatulence. Under these circumstances, we have recourse to astringents and tonics, together with the occasional use of sudorifics and opiates. The employment of astringents in Diarrhœa we do not, however, conceive to be very frequently necessary; and it is found, both with respect to the class of remedies and to opium, that if they do not check the complaint by the exhibition of a few doses, no considerable benefit is to be expected from them. The valuable compound of opium and ipecacuanha, which we have so frequently referred to under the title of Dover's powder, is a very useful remedy in long protracted Diarrhœa, especially when in conjunction or alternating with purgatives. Considerable advantage has been gained by the use of warm clothing, and particularly of flannel worn next to the skin, in those who are subject to frequent attacks of Diarrhœa; and sometimes it has appeared that the warm bath, or even the removal to a milder climate, has been of permanent utility.

Sect. II. *Cholera.*

Cholera consists in the vomiting and purging of bilious matter, attended with painful griping, and with cramps of the legs. It is sometimes difficult to draw the line between this disease and Diarrhœa, although, when it exists in an acute state, it is easily distinguished by the nature of the evacuations. It seldom occurs in this country, except in the autumnal months, and it is then found to be the most prevalent in the hottest seasons; but is generally observed to come on rather after the period of the greatest heat than during its continuance.

The leading symptoms of the disease seem to mark it as arising from some peculiar condition of the bile, and the time of its invasion favours the idea, that external temperature has an important influence in its production; but we are scarcely able to explain the nature of the connexion between these circumstances, or to shew in what manner the heat of the weather produces the change in the state of the bile, or indeed what is the exact nature of the change which it experiences. Cholera is a violent disease, and one which is very rapid in its progress; reducing the patient in the space of a few hours to a great degree of debility, and, if not checked by the appropriate remedies, proving suddenly fatal.

Its cure is to be effected, by completely evacuating the intestinal canal of the irritating matter which appears to be the exciting cause of the disease, and this is generally accomplished merely by the exhibition of mild diluents, which may be taken as copiously as the stomach will receive them. When the acrid bile has been entirely removed, we then endeavour to allay the irritation by opiates, and afterwards to recruit the exhausted powers of the system by gentle stimulants and excitants. To allay the griping pains fomentations may be applied to the abdomen, and sometimes immersion in warm water will be found highly grateful to the feelings of the patient, when it can be commodiously applied. After the violence of the disease has subsided, the patient is left in a state of great weakness and langour; but by the proper regulation of the diet, and by avoiding all unnecessary causes of excitement, the strength is generally restored with more rapidity than might have been imagined from the degree of exhaustion. Bitters and tonics of various kinds are generally administered for the purpose of strengthening the digestive powers, and of these colombo is the one which is found to be the most useful.

Sect. III. *Lithiasis. Stone.*

We have placed calculous complaints as forming a genus under the order of the Apocenoses, because they depend upon the formation of certain substances in the urinary organs, which originate, in the first instance, from an irregularity in the action of the secretory vessels of the part. The disease is characterized by uneasiness in the region of the kidney, the bladder, or some of the passages connected with them; by a difficulty and pain in passing the urine; frequently by a deposition of calculous matter from this fluid; or by the presence of a calculus in the bladder, as ascertained by the introduction of the sound.

The exciting or predisposing cause of the disease is probably, in all cases, a derangement of the digestive organs, by which the fluids undergo some change in their nature, so that, in passing through the kidney, certain substances are secreted that concrete together into solid masses. These, according to their form, and the situation where they are deposited, produce various distressing symptoms, that are immediately to be attributed to their mechanical bulk, either pressing upon the contiguous parts, or obstructing the discharge of the natural excretions. Very minute attention has been paid of late years to the chemical analysis of urinary calculi; and, according to the most accurate experiments, we may arrange them under the following heads: 1st, The lithic calculus; 2d, The bone earth calculus, consisting principally of phosphate of lime; 3d, The ammoniaco-magnesian phosphate; 4th, The fusible calculus, consisting of a mixture of the two former; 5th, The mulberry calculus, composed of oxalate of lime; 6th, The cystic, consisting of the peculiar substance called cystic oxide. To these we may add the alternating calculi, those that are formed of different substances arranged in alternate layers; and the compound calculi, composed of different ingredients mixed together without any regular order.

As urinary calculi are properly extraneous bodies, and do not possess any vital properties, it has been always considered a most important point to discover some chemical agent, by which they might be rendered soluble, and in this way discharged along with the urine. Until very lately all the attempts that had been made of this kind were entirely empirical, and, notwithstanding various flattering accounts which, from time to time, had been laid before the public, were altogether abortive; but since the greater accuracy of modern chemistry, their nature has been thoroughly investigated, and we are well accquainted with means by which most of them may be readily dissolved out of the body. It still, however, remains a doubtful point, whether, while they are in the bladder or the urinary passages, any re-agent taken into the stomach can be carried along the circulation so far, unaltered, as to be capable of acting upon the calculus through the intervention of the urine; and, upon the whole, we are disposed to think that but little can be expected from this mode of proceeding. But, although we may fail in this object, there are still two methods of relieving the disease; one indeed, which is extremely painful, and after all merely palliative, viz. by cutting into the bladder, and removing the calculus; the ether, which, if it can be accomplished, must be regarded as the more desirable plan, is by counteracting that state of the digestive organs which gives rise to the disease. Upon the whole we may conclude, with respect to this latter point, that whatever remedies would, in other circumstances, tend to improve the process of digestion, and establish the healthy action of the intestinal canal, will be equally serviceable in preventing the formation of calculi. But, besides this general view of the subject, it will be necessary for us to examine the state of the urine in the individual cases of Lithiasis that present themselves; because in most of them we can distinctly perceive the existence of two conditions of the system, which are very different from each other, produce different effects, and may probably require different remedies. In one of these a calculus is formed of an acid nature, which it may therefore be supposed will require alkaline medicines for its prevention; while in others there is a tendency to the formation of a calculus in which an alkaline earth predominates, and which may therefore be supposed to indicate the employment of acids for its prevention. Upon this principle, we have been directed, in the treatment of Lithiasis, first to examine into the state of the urine, and into the nature of the calculous deposition, or of any solid matter which may have been discharged, and to administer either the carbonates of the fixed alkalies, or diluted muriatc acid, according to the result of the examination. Besides these, we are to give purgatives freely; to enjoin a plain diet, especially abstaining from fermented and spiritous liquors; and, in short, to adopt that system of regimen which is the best calculated to induce a healthy action of the stomach and bowels—a circumstance which we are inclined to think is much more important than any direct chemical effect that can be produced on the fluids. The propriety of an operation will depend upon the urgency of the pain, or the other symptoms arising from the mechanical bulk of the stone. We shall only remark, that sometimes a large calculus in the bladder may be borne with tolerable ease, when, by the use of the proper remedies, it can be prevented from increasing in size; this probably arises from its more prominent and irritating parts being rounded off, and the organ becoming accommodated to its reception.

Sect. IV. *Leucorrhœa.*

We have placed Menorrhagia among the Apocenoses, because there is reason to suppose that the menstrual discharge is, strictly speaking, a secretion; owing, however, to the nature of its symptoms and treatment, we have enumerated it among the Hæmorrhagies, and have given directions for its management in that part of our system. Leucorrhœa, which consists in an increased secretion from the mucous glands of the uterus, is characterized by the appearance of the discharge; by pain in the loins; loss of appetite; general debility; and wasting of the flesh. The discharge is sometimes of so acrid a nature as to excoriate the parts on which it lodges, and occasionally it even communicates the same symptoms by contact to a second person.

It is not very easy to ascertain either the exciting or the proximate causes of Leucorrhœa. Whatever stimulates the parts in an excessive degree has been conceived to give rise to the complaint; but, on the other hand, it has also been attributed to a variety of circumstances that tend to debilitate the system. Perhaps we ought to ascribe the affection to general debility, combined with local excitement. The debilitating effect of the complaint is much greater than might have been expected from the quantity of matter discharged, indicating that the complaint is to be referred chiefly to some constitutional action, depending upon the relation which the uterine system bears to the other parts of the animal economy. The complaint is often sympathetic of some structural disease of the uterus, and is then more unfavourable in its prognosis, and often more distressing in its immediate effects; but when it exists in its simple form, although, as we have remarked above, it is considerably debilitating, and proves a source of much inconvenience, it is seldom to be regarded as dangerous.

The indications of cure are not very obvious, and the effect of remedies is uncertain. The usual method has been to employ tonics and stimulants; but we are frequently disappointed in our expectations of benefit from them, and, under certain circumstances it would appear, that the opposite plan of treatment is more successful. We occasionally derive advantage from the topical application of astringents, such as solutions of tan, alum, or sulphate of zinc; but it may be doubted, whether the effect of these substances, as essentially consisting of cold fluids, is not as powerful as any specific operation derived from the nature of their ingredients. Cantharides have lately been recommended in Leucorrhœa, both taken internally, and applied externally in the form of blisters, to the parts contiguous to the uterus; but it may be doubted how far they will be found to correspond with the high character that has been given of them. As there is generally a torpor of the intestines, it is obviously necessary to employ purgatives; and it is supposed that some particular benefit is obtained from those that are of a stimulating nature, as the resins and extracts, but we are disposed to doubt the correctness of this opinion. Violent exercise of all kinds appears to be injurious; and we should avoid all those circumstances which excite the circulation without increasing the strength of the system, such as stimulating liquors, luxurious diet, and heated apartments.

Sect. V. *Icterus. Jaundice.*

The second order of the Parecrises consists of the Epischeses, those diseases in which there is a deficiency of some of the secretions and excretions. The first genus of this order is Obstipatio, an affection which is generally symptomatic of some derangement of the stomach, the liver, or other viscus concerned in the process of digestion, but which may depend upon a torpor of the intestinal canal itself, and which is then to be obviated by the regular exhibition of purgatives, in the selection of which we must be guided more by the particular circumstances of the case, than by any general rules that can be laid down upon the subject. The operation of these remedies is always much promoted by an attention to diet, pure air, and exercise.

We have placed Icterus in the same order, although it probably, in some cases, at least, depends rather upon the retention of bile, than a deficient secretion of it, a defect which generally happens in consequence of some obstruction in the passages through which the fluid descends, in the natural state of the parts, into the duodenum. The most remarkable symptoms of Jaundice depend upon the absorption of bile into the circulation after it had been previously secreted; upon this depends the peculiar colour of the skin and the cornea, arising from the serum of the blood being tinged with bile, which is carried into it by the lymphatics of the liver. To the same cause, the bile being actually present in the blood, we may ascribe the bitter taste of the saliva, and the yellow colour which is communicated to the urine, as well as its property of dyeing substances that are immersed in it. The bile being thus diverted from its natural course, the deficiency of it in the intestines produces a train of symptoms in the digestive organs; the fæces become whitish, or of a clayey appearance, and the bowels torpid; while the appetite fails, and the whole process of digestion and assimilation is deranged. There is also pain in the region of the liver, and the patient experiences an unusual degree of lassitude and general weakness. In what way the phenomena of Jaundice are connected together, whether a mere obstruction to the passage of the bile from the liver to the intestines is the primary cause of all the other symptoms, whether there is some original defect in the secretion of the bile itself, or some torpor in the digestive organs or their appendages, may be doubted; nor, supposing it proved that the disease proceeds from a mechanical cause, are we able to determine how the deficiency of bile in the intestinal canal can produce the effects that we observe on the digestive process. In many cases Jaundice evidently depends upon some disease in the structure of the liver, by which its functions are permanently injured, sometimes by an extraneous body filling up the duct, or pressing upon it; but there are cases in which, so far as we can judge, it appears to arise from some cause that is more strictly idiopathic, and of a less mechanical nature.

In the cure of this complaint, we are first to ascertain whether it depends upon a scirrhus of the liver, or any other structural disease of this organ, in which case our remedies must be obviously directed to this circumstance. If we suspect it to arise from a mere mechanical obstruction, we generally have recourse to purgatives; and these remedies are probably the best that we can employ in Jaundice that is more strictly idiopathic. The more active purgatives are usually found to be the most efficacious, and it is generally thought desirable to combine them with calomel. An emetic is often indicated by the state of the stomach; and by this remedy we not only free this organ from its load of oppressive contents, but it appears that the agitation which is produced by the act of vomiting occasionally removes obstructions from the ducts of the liver. The disease is sometimes attended with very acute pain, for which opiates are necessary; and besides the immediate relief which they afford, they sometimes tend to the radical cure of the complaint, by relieving certain spasmodic contractions of the parts which aggravate the disease, by increasing the obstruction to the passage of the bile along its natural channels. After the disease itself has been subdued, the impaired state of the digestion often renders it necessary for us to have recourse to stomachics and tonics, of which colombo appears to be the most useful. Considerable benefit is sometimes produced by a long continued employment of the saline mineral waters, to which the fresh air and exercise which form a part of the usual regimen in such cases will materially contribute.

One of the causes of Jaundice, depending upon a mechanical obstruction to the passage of the bile, is the formation of the peculiar bodies called biliary calculi, giving rise to the disease of Cholelithia or Gallstone, a disease which properly belongs to the order of the Apocenoses, but the consideration of which we have deferred to this place, on account of its connexion with Jaundice. These substances are partly composed of inspissated and hardened bile, and partly of a crystalline animal matter, which concretes into rounded masses, formed in concentric layers, and possessed of specific chemical properties. In what way they are generated, or what particular states of the liver and its secretions are favourable to their production, is not ascertained, nor are we acquainted with any method by which their formation can be prevented. When they are impacted in the ducts of the liver, they cause very acute pain, which is generally referred to the pit of the stomach, and is often attended with severe vomiting, and by this operation the obstruction is occasionally removed; the same effect is sometimes produced by brisk purgatives. Opium and warm fomentations relieve the pain, and likewise the spasmodic contractions, which, as was remarked above, seem to exist in these cases, and tend to aggravate the complaint. There are instances in which the distention produced by Gallstones is so great as to produce inflammation, when bleeding must obviously be had recourse to, at the same time that we may try the warm bath and emollient injections.

Sect. VI. *Amenorrhœa.*

Ischuria, or a difficulty in the excretion of the urine, is perhaps in all cases a symptomatic affection, either occurring in connexion with some other more general disease, as Dropsy, or depending upon some obvious mechanical obstruction, as in Lithiasis. We shall therefore pass on to Amenorrhœa, or the deficiency of the menstrual discharge. It occurs under two forms, that of retention and of suppression: the first, where the discharge does not make its appearance at the proper period of life; the second, where, after it has appeared, it does not return at the usual intervals. There is another affection which ought perhaps to be regarded as a mere variety of Amenorrhœa, in which the discharge takes place at the proper times, but is in small quantity, and is attended with considerable pain: this has received the name of Dysmenorrhœa. When Amenorrhœa, in any of its forms, has continued for some time, it produces various constitutional derangements; there are pains in different parts of the body, especially in the neighbourhood of the uterus; the appetite fails, the bowels are torpid, the head is oppressed, Anasarca supervenes, the breathing is short, the pulse is weak, and the whole body becomes languid and enfeebled. In some cases, particularly in those where the discharge does not take place at the proper age, there is a remarkable sallowness of the complexion, from which circumstance the disease has obtained the name of Chlorosis; it is likewise attended with a singular tendency in the patient to take into the stomach various articles of an indigestible nature, which would seem to be the mere effect of caprice, did we not observe this morbid appetite to exist, where we have no reason to suspect this disposition from any other circumstance, and where the stomach is evidently in an unnatural state. The proximate cause of these complaints is evidently, in the first instance, the same, a defect of power in the vessels of the uterus, by which they are unable to propel the blood into the capillaries with due force and in the proper quantity. In what way this condition of the capillary vessels produces the general symptoms is perhaps not easy to explain; and indeed it may be suspected, that, at least in a great number of cases, the peculiar state of the uterus is rather the effect than the cause of the constitutional irregularity.

But whatever may be our determination upon this point, it does not affect the principles upon which we proceed in our treatment of Amenorrhœa, which is to excite the system generally, and the uterus in particular, by the use of those means which may increase the action of the arterial system, and especially of the uterine vessels. The state of the bowels obviously requires purgatives, and those of a stimulating kind; such as the resins and more acrid extracts, scammony, aloes, colocynth, &c. The degree of flatulence which is generally present, indicates the employment of what have been termed carminatives; and when there is much pain or irregular action of the parts, we may prescribe antispasmodics, of which perhaps the most efficacious is asafœtida, with an occasional opiate. Exercise, and especially horse-exercise, as much as can be borne without exhaustion, is a necessary part of the regimen; and the diet should be as nutritive as the patient can bear, without inducing indigestion or any degree of febrile excitement. We have hitherto taken no notice of that class of remedies that are styled emmenagogues, because we are extremely doubtful whether there be any to which this title ought to be applied, except to some substances, the action of which is so violent as not to be admissible into practice; we consider the savine to be of this description. Perhaps there is nothing which is better entitled to the specific appellation of an emmenagogue than electricity, and this application may be safely tried in conjunction with purgatives, and the other treatment that has been mentioned above. The warm hip-bath, or even warm water applied to the feet, frictions with the flesh-brush, and warm clothing, are generally thought to be serviceable. Besides these remedies, which appear to be more particularly indicated by particular symptoms, we often find it necessary to use stimulants and tonics, as the various kinds of bitters, and the preparations of iron; with respect to the latter medicine, it should not be employed until the bowels are rendered completely soluble, and in all cases it may be proper to combine it with aloes, or with some of the purgative resins or extracts.

CHAP. VI.

Paramorphiæ. Local Structural Diseases.

Having now, in our five first classes, gone through the different diseases which proceed from primary affections of the systems of the blood-vessels and the nerves, the mental faculties, the organs of nutrition, and those of secretion, we now come to the diseases which are of local origin. These form the two classes of the Paramorphiæ and the Ectopiæ; the first denoting a morbid change of structure, the latter a mechanal displacement of the parts concerned. The greatest number of these diseases fall under the province of surgery; they frequently require the assistance of some manual operation, or of external applications; and although they are often accompanied by constitutional affections, yet these are obviously sympathetic, so that our main attention is to be directed to the topical derangement.

We have divided our class of Paramorphiæ into Phymata and Phtharmata; the first including tumours of all descriptions; the second denoting an alteration in the substance or structure of the part, as where a membrane is converted into a bone, where a soft part becomes rigid, or a hard part becomes soft and flexible. Of the different genera which compose this order, perhaps the only one which can properly be considered as falling under the province of the physician, is that which consists of the organic affections of the heart. Besides the inflammation of this viscus, which has been already treated of among the Phlegmasiæ, it is subject to many other organic derangements; its valves, and their appendages, which are subservient to the mechanism of the circulation, are liable to become ossified, and its large arterial trunks are subject to the same affection. Sometimes, without assuming the bony texture, the membranous parts become rigid and inelastic; sometimes, on the contrary, the muscles that compose the substance of the heart appear to lose their tone or contractile power, and are relaxed, so as to admit of the ventricles becoming distended to an enormous size, and besides these, there are different kinds of mal-conformation in the original construction of the heart, which interfere with the performance of its appropriate functions. The symptoms that are produced are very various, and often are difficult to be accounted for; they seldom enable us to predict in what state the parts will be found after death, and even when we have ascertained this point by dissection, it is not always easy to reconcile the symptoms with the actual disease. A very remarkable circumstance respecting diseases of the heart, is the disproportion between the violence of the symptoms produced, and the actual alteration in the organ; even in inflammation, which has been so acute as to induce suppuration, and finally to prove fatal, that state has frequently not been previously indicated by pain in the part, or even by the state of the pulse. We have already had occasion to remark, that the disease of Angina Pectoris is frequently, if not in every instance, combined with a structural derangement of the valves, orifices, or great vascular trunks contiguous to the heart; and we have reason to believe that many affections, which are referred to the lungs or the stomach, originate from the same cause. It must be obvious that the cure of these diseases is, for the most part, beyond the reach of the medical art, and that in most of them we are not able to do much even in palliating their effects. The only general principle upon which we can proceed is, to endeavour to moderate the force of the circulation without weakening the vital powers; by avoiding violent exercise and sudden motion, by a strict plan of temperance, by keeping the mind in a tranquil state, and, in short, by preserving as uniform a degree of motion as possible in the parts concerned in the propulsion of the blood. Unless there should be any peculiar excitement, bleeding is not indicated, nor are purgatives adviseable as a general practice, unless there be an obstruction in the bowels, or some feeling of indigestion; for we may remark, that in order to prevent a plethoric state of the system, it is much more desirable to avoid repletion of the stomach, than to endeavour to obviate its effects. Blisters and issues applied to the chest have been found useful in relieving affections that have certainly seemed to proceed from an organic disease of the heart, and it will therefore be proper to try their effect. As it is so difficult to substantiate the existence of these complaints, we are, for the most part, reduced to the necessity of prescribing for particular symptoms; and although in this way we can expect to do little more than palliate, it must be admitted that very unexpected cures have occasionally resulted. Cases have sometimes occurred, where every circumstance seemed to indicate a serious organic affection, but where, by the exhibition of some medicines that improved the state of the stomach, all the alarming symptoms have vanished, and the patient has regained a state of perfect health.

With these observations we shall conclude the sketch that we proposed to offer of the principles of medicine. In a work expressly intended for general perusal, we have abstained from entering into minute details, convinced, as we are, that popular treatises of practical medicine are seldom useful and often dangerous. We have endeavoured to produce a work which may mark the present state of medical science, and which may serve as a basis for those who are desirous of entering more minutely into the subject. We have given a concise view of most of the doctrines which have either produced any considerable effect upon the state of medical practice, or which, from their real merits, seem to be entitled to our attention. If on many points we have dissented from the opinion of our predecessors, our apology must be that they, in their day, dissented as much from those who went before them; and if it be objected that we have frequently confessed the insufficiency of our art, and have left many formidable diseases without indicating an effectual mode of treatment, we may reply, that the science of medicine would probably have attained a greater degree of perfection, if writers had more strictly confined themselves within the limits of experience and correct deduction, and had not thought it incumbent upon them to point out a remedy for every disease. (α)

INDEX.

MEDINA en Nebi, a city of Arabia, in the district of El Hedjaz, or the *land of Pilgrimage*, which comprehends the *Arabia Petræa* of the Ancients, but beyond the confines of the Beled el Haram, or *holy land of Islam*, a territory that none, excepting Mahometans, are allowed to enter. This city stands on a fertile spot, in a mountainous desert. The mountains, which constitute a prominent feature in the whole land of Pilgrimage, are highest in its vicinity. Water is scarce throughout the territory, being obtained from a few inconsiderable springs and deep wells; but here and at Mecca the rain water is preserved by the inhabitants in cisterns, and the neighbouring gardens and plantations are supplied plentifully with it. The tree yielding the real balsam of Mecca, which is called *belsan*, grows in the surrounding desert, though it is not obtained at Mecca itself.

Medina is small, and surrounded by a slight wall, which seems to have been strengthened when the inhabitants were menaced by an army of sectaries a few years ago. It is a place of no importance, except from containing the sepulchre of Mahomet, the approach to which was always strictly interdicted to Jews and Christians; but the inhabitants enjoy the privilege of exemption from the impost paid to the scheriff of Mecca, the natural lord of the country, and the tenth exacted by the sectaries now alluded to. The Turkish emperor claims the sovereignty of Medina and the neighbouring territory, and had two officers in the city; but the scheriff of Mecca, enjoying an independent power, held the real supremacy, and had a vizir in Medina.

The tomb of Mahomet is inclosed by an iron grating within the precincts of a mosque of indifferent structure, and is surrounded by a rich brocade in letters of gold, on a green ground, the colour of the faithful. Neither the tomb nor the mosque are distinguished by any magnificence; but an immense treasure had accumulated for ages, the pearls and precious stones in which exceeded all estimation. Near to the tomb is seen an opening, which the Mahometans affirm is for the purpose of receiving Jesus Christ, as they believe he is yet to return, and die at Medina. Here also are the tombs of the Caliph Othman, and other friends or descendants of the prophet; and the chair or pulpit from which he was accustomed to preach, is yet preserved with superstitious care, to be used at festivals. A fable was formerly prevalent, that the tomb was suspended in the air between two magnets, or without any visible support. Poncet, a French physician, who designed visiting Medina about the year 1700, and travelled much in the East, declares that he visited a monastery of Abyssinia, for the purpose of seeing a similar phenomenon. There he beheld a round golden staff, about four feet long, suspended in the air; and, to detect any artifice, he requested the abbot to permit his examining more narrowly whether there was not some invisible prop or support. "For my better assurance," says he, "and to take away all doubt, I passed my cane over it, and under it, and on all sides, and found that this staff of gold did truly hang of itself in the air." It is not improbable, therefore, that some deception was practised in suspending this celebrated sepulchre, which those who determine on accounting for every thing conceived was accomplished by magnets. The tomb was enclosed by the iron grating, and was also guarded by 40 eunuchs, in consequence, it is commonly believed, of an attempt to carry off the bones of the prophet.

Medina and Mecca are two places of pilgrimage, resorting to which confers great distinction on the devout Mahometans; but it appears that the latter is more frequented. Nevertheless, a caravan annually repairs to Medina from Damascus, the principal purpose of which is to carry a rich carpet from the Turkish emperor for the tomb of the prophet. It travels under the direction of the pacha of that city, as prince of the pilgrims, is guarded by troops and artillery, and accompanied by a great number of women.

Of later years, both the religious and political state of Medina underwent an important alteration; nor can its condition at the present time be precisely ascertained. The environs of the city gave birth to a Mahometan sheik, named Abdoulwehhab, about the year 1720, who, after pursuing his studies here, contemplated great innovations on certain principles of the Musselman faith. But finding Medina itself unsuitable to his views, he left it to make a proselyte of Ibn Saaoud, prince of the Arabs, whose son Abdelaaziz endeavoured, in succeeding years, to subdue all the neighbouring countries. The Scheriff of Mecca, unable to resist his forces, retired to Medina in 1802; but the city proving untenable, he again withdrew. However, it withstood a body of troops sent from Mecca, which had been pillaged previously, and their commander Saaoud was obliged to retreat to Draaija, the capital of the sectaries, seventeen days journey east of Medina. But Saaoud having renewed the attack after his father had been assassinated in 1803, rendered himself master of Medina in 1804, where his followers shut and sealed the doors of the temple, destroyed all the ornaments of the sepulchre, and took possession of the vast treasures which superstition had accumulated. In 1805, the great caravan from Damascus obtained access to the city only by means of heavy sacrifices; and the reformers signified to the pasha, that in future it should come no longer under protection of the Turks, or accompanied by troops, trophies, music, or women, but that it should consist of pilgrims exclusively. The caravan having attempted to travel thither next year, without strictly conforming to these injunctions, had hardly reached the gates of Medina when it was obliged to retire in disorder, persecuted and annoyed by the sectaries. Devotion to the person of the prophet being prohibited as sinful, the reformers refrain from visiting his tomb; and they have destroyed the sepulchres, chapels, and temples erected in honour of saints. In the year 1807, the whole priests, servants, and slaves belonging to the mosque of Mahomet's tomb at Medina, were commanded instantly to quit the city, as also all pilgrims and soldiers, together with the Turkish judge. A complete revolution, both religious and political, was thus accomplished; but we have understood, that in the year 1817 or 1818 the Emperor of Turkey, in order to regain his influence in Arabia, sent a large military force against the reformers, by which they were defeated, and their leader, being taken prisoner, was carried to Constantinople, and there put to death. Lat. 24° North, Long. 40° 10′ East. 240 miles north of Mecca. (*c*)

MEDITERRANEAN Sea, is the largest inland sea in the world, forming the southern limit of nearly the whole of Europe. It is about 2000 miles long from east to west, and has an average breadth of from 400 to 500 miles. From the Bosphorus a strong current sets into the Mediterranean; at the Straits of Gibraltar another current flows in from the Atlantic; two weaker currents flowing outwards along the northern and southern shores. The tides in the Mediterranean are very small and irregular.

Dr. Marcet has lately shewn, that the water of the Mediterranean contains rather more salt than the ocean. This fact has been explained, upon the supposition that the Mediterranean is not supplied by the rivers which flow into it with a quantity of fresh water sufficient to replace what it loses by evaporation under a burning sun, aided by a powerful radiation from the African shores, and the parching winds blowing from the adjacent deserts. Philosophers have, therefore, attempted to explain why this sea does not gradually increase in saltness, and indeed be ultimately converted into saturated brine. This has been ascribed to an under current of water, salter than the ocean, which runs out at the Straits of Gibraltar, and unloads its waters of their excess of salt. This idea of a submarine current is countenanced by the fact communicated to Dr. Marcet by Dr. Carmichael, on the authority of the British consul at Valentia, that some years ago a vessel was lost at Ceuta, on the African coast, and its wreck afterwards thrown up at Tariffa, on the European shore, fully two miles west of Ceuta.

A similar fact is stated by Dr. Hudson. "In 1712, M. de L'Aigle, of the Phœnix of Marseilles, giving chace near Ceuta Point to a Dutch ship, came up with her in the middle of the Gut, between Tariffa and Tangier, and then gave her one broadside, which sunk her. A few days after the sunk ship, with her cargo of brandy and oil, came on shore near Tangier, at least four leagues to the west of the place where she sunk, and directly against the strength of the current; which has persuaded many men that there is a *recurrency in the deep water in the middle of the Gut, that sets outward to the grand ocean, which this accident very much demonstrates.*" *Phil. Trans.* 1724, vol. xxxiii. p. 192. See also *Phil. Trans.* 1819, p. 177; and *Edinburgh Philosophical Journal*, vol. i. p. 236, and vol. ii. p. 358.

MEDWAY. See England, and Kent.

MEKRAN, or Mecran, is a province of Persia, stretching from Cape Jask to the frontiers of Scind, along the Indian Ocean, which bounds it on the south. On the north it is bounded by Seistan and Arokaje; on the east by Scind; and on the west and north-west by Kerman. Mekran is divided by a range of mountains running from east to west. The northern part has got the name of *Balouchistan*. To the east there is a small independent state called *Lus*. Balouchistan is again subdivided into the seven following provinces or districts: *Jhalawan*, the most southern, and *Sarawan*, the most northern, both of which are extremely mountainous, and in general barren, though some of the vallies are capable of high cultivation, and produce, in favourable seasons, very abundant crops.—*Cutch Gandava*, which is about 150 miles long, and 40 or 50 broad, is chiefly low country, having a rich black loam soil, and producing all sorts of grain, besides cotton, indigo, and madder.—*Anund Dejel*, to the northward of the former, whose climate and soil are excellent.—*Shal* and *Muslung*, which are of very inconsiderable extent, but distinguished for the excellence and cheapness of their productions; and *Zuhree*, which is well peopled, and has the name of being the most civilized district of Balouchistan.

The province or district of *Lus* is of a circular form, and nearly surrounded by mountains, which separate it from western *Mekran*, *Balouchistan*, and *Scind*. The country itself is flat and sandy, and remarkably fertile in every description of grain. It has two small rivers, *Wudd* and *Pooralee*, (the ancient Arabius,) which, rising in the mountains near Bayla, falls into the ocean at Sonmeany, the principal sea-port of Lus. In order to obtain water, the inhabitants of this district, who are chiefly fishers, are obliged to dig holes in the sand, and having taken a supply, they fill them up immediately, lest the water should become salt, which it certainly does when the holes are left open.

Punjgoor, or *Punger*, which is remarkable for its dates, is a small, fertile, and well peopled district. It lies at the distance of about ten days journey, in a direction north north-east from Kej, the capital of Mekran, the whole of the mountainous tracts to the westward forming the southern boundary of the sandy desert, and on the parallel of Punjgoor. It has obtained the general name of *Wushutee*, or *Mecch*. Nooshky is a small sandy barren district, occupying an area of about 36 square miles, whose inhabitants subsist chiefly by plunder. Gurmsyl is also a very small but extremely fertile district, and is about five days journey to the north-west of Noosky. It is a narrow strip, in some places frequently not exceeding half a mile in breadth, and being flanked on both sides with high banks, it resembles the dry bed of a river. It derives its extraordinary fertility from the annual overflowing of the river *Heermund*.

Some of the districts in this province are almost entirely mountainous. The northern and southern parts of Balouchistan are described as a confused mass of tremendous hills, extending in length about 350 miles, but varying considerably in breadth; and the small state of Lus is bounded on three sides by one stupendous chain. In Western Mekran, the mountains run parallel with the shore, at the distance of eight or ten miles. At Chobar, however, and Cape Jask, they approach the coast. This chain attains its greatest elevation at Surku, the streams on the north side flowing towards the Persian Gulf, and those on the south to the Indian Sea.

The rivers in Mekran present a singular appearance during the summer months, being then almost quite dry. The following are the principal of which we have received any account: The Neam Khor, or salt river, which falls into the sea at Tiz. The Cajoo river, which rises in the hills at Suroo, and joins the ocean thirty miles west of Chobar, between *Roasim* and *Tank*. The Bunpoor river, whose course is from east to west. After its confluence with another stream which traverses the fertile plains of Lushar, it loses itself in the sands about forty miles to the westward of the town of *Bunpoor*. When visited by Captain Grant in the month of February, it was 20 yards wide and 3 feet deep.

The population of Mekran consists of many different tribes and independent chiefs, of which the Balouches are the most numerous. A corrupt Persian, mixed with Scindi, is the common language of the country. The whole force of Mekran may amount to about 25,000 men. Lead and iron are produced in the mountains to the south of Kelat. Some gold and silver have been found at Nal. Copper, tin, antimony, sulphur, saltpetre and marble are also found. See Kinnier's *Geog. Mem. of Persia*, p. 202—225.

MELANCTHON, Philip, the celebrated friend and coadjutor of Luther, was born in Bretten, a town of Saxony, on February 16, 1490. His father, George Schwartzerd, (which was the German family name,) held the office of commissary of artillery, and was distinguished by his ingenuity in the invention of military instruments, as well as by the strictness of his piety and correctness of his morals. The care of Melancthon's early studies (in consequence of his father's public engagements) was entrusted to his maternal grandfather, John Reuter, who long filled the office of mayor in Bretten. He was at first sent to a public school in his native town; but, a contagious disease having appeared among the scholars, he was soon placed under private tuition. He was instructed in the Latin language by John Hungarus, (who afterwards became a protestant preacher,) and gave early indications of his great natural capacity. He studied the Greek language with equal diligence and success at Pforzheim, under George Simlerus; and during the course of his studies in this place, had frequent opportunities of receiving the friendly advices of John Reuchlin, or Capnio, as he is more generally called, who was one of the principal restorers of learning in Germany, and who was greatly attracted by the promising talents and studious habits of young Melancthon. At the age of twelve he wrote several pieces in Latin verse, and in the following year composed a humorous comedy, which he dedicated to Capnio, from whom he received, on that occasion, the name of Melancthon, which signifies in Greek what Schwartzerd does in German, namely, "black earth." After a residence of two years at Pforzheim, he was sent to the University of Heidelberg, where he soon became distinguished by his talents, application, and amiable dispositions. He wrote most of the public harangues delivered at the university, during his attendance there; and was entrusted with the education of the two sons of Count Leonstein. The situation of Heidelberg appearing to be unfavourable to his feeble constitution of body, and his mind being chagrined by the refusal of a higher literary degree, on account of his youth, he left that university after a residence of three years, and removed to that of Tubingen, which was then celebrated for its eminent professors in every branch of literature and theology: There he devoted himself particularly to mathematics, jurisprudence, logic, medicine, and theology, and, at the age of seventeen, was created doctor in philosophy, or master of arts. He soon afterwards became a public lecturer in the university, and excited general admiration by his profound knowledge and elegant taste in the Latin classics. He was at this period the restorer of Terence, whose poetical compositions had hitherto appeared in a prosaic form; and he speedily attracted the attention of the greatest scholars of the age. He was particularly eulogized, when only a youth of eighteen, by the learned Erasmus, whose works abound in the strongest testimonies both to the eminence of Melancthon's attainments, and to the excellence of his character.

The history of his religious principles cannot be detailed with the same precision as that of his literary progress; and the principal fact, illustrative of this point, is the gift of a small Bible from his friend Capnio, upon which he was accustomed to note such explanatory hints as occurred to his own mind, or as pleased him in the works of others, and which he made his constant companion, particularly during the service of public worship. After remaining six years at Tubingen, he removed to the university of Wittemberg, where he was appointed to the Greek professorship; and where he attracted such numbers of students, that he is said to have sometimes had an audience of 1500 persons. Here he soon became the intimate friend and invaluable associate of Luther, by whom he was consulted on all occasions, and to whose great cause he rendered the most essential service by his literary resources and temperate counsels. He took a leading place in the improvement of philosophical studies, uniting the study of the Aristotelian method, with all that was valuable in the writings of the Stoics and Platonists, and thus forming a kind of eclectic system, which was named from him the Philippic method, was speedily introduced into all the Lutheran schools, by abridgements from his own pen on the various branches of philosophy. After the celebrated disputation at Leipsic between Luther and Eckius, at which Melancthon was present, he applied himself more intensely to the study of the scriptures, and the illustration of pure Christian doctrine. Having been assailed by Eckius in an abusive letter, on account of the opinions which he had expressed of the different disputants, he published a reply, drawn up with so much elegance of language, acuteness of argument, and mildness of spirit, that it proved extremely favourable to the cause of his friend. In 1520, he married a young woman of a reputable family in Wittemberg, and of a character in every respect congenial with his own. They soon became distinguished patterns of genuine piety and Christian beneficence. His house was crowded by paupers, who were never sent away empty; and his time was beset by equally numerous applicants for his advice, his recommendation, his literary aid, or merely for the pleasure of seeing so celebrated a person, to all of whom free access was granted. But, however devoted by principle and feeling to literary leisure and domestic retirement, Melancthon was frequently called by his sense of duty, to encounter that publicity, and to share in those contests, which he would otherwise gladly have shunned. During the period of Luther's seclusion in the castle of Wurtenberg, he found himself placed at the head of the reformed cause, and was fully aware of the high responsibility attached to such a situation. He discharged, at the same time, many of those clerical duties which belonged to the office of Luther; and notwithstanding all the sensibilities (we may almost say the hypochondriasm) of his nature, he often appeared in the front of the contest, which was now thickening on every side. In answer to the condemnation of the reformer's principles, published by the divines of the Sorbonne in 1521, he wrote a small but satirical pamphlet, entitled, "Adversus Furiosum Parisiensium, Theologastrorum decretum pro Luthero Apologia;" and another in the same year against Placentinus, or rather Emser, in which he details the history of the Lutheran controversy, and refutes the calumnies of the anti-reformation party. He was busy also in his university labours, exciting the youth under his care to the diligent study of Christian truth in the writings of the apostle Paul; and about the same time he produced his celebrated work, entitled, *Theological common places*, which excited great attention, and obtained an extensive circulation, not only in Germany, but also in France and Italy. It was published in Venice under the name of *Philippo de Terra Nera*, (the Italian translation of the word Melancthon); and, under this designation, was either approved, or at least uncensured; but, as soon as it was known to be the production of Philip Melancthon, it was instantly suppressed by order of the Inquisition. This work was extolled by Luther as the best book next to the Holy Scriptures, and recommended along with his own translation of the Bible, as sufficient together for the formation of a good divine. His pen was much employed in revising the translation of the New Testament by Luther; and particularly in comparing that of the Old Testament with the Septuagint version. About the middle of the year 1522, Luther having secretly got possession of a manuscript commentary by Melancthon on the Epistle of Paul to the Romans, printed it without the author's knowledge, and sent him a copy, with a very characteristic apology prefixed, of which a few sentences will not be thought unworthy of being transcribed. "Martin Luther to Philip Melancthon, grace and peace in Christ. 'Be angry and sin not. Commune with your own heart upon your bed and be still.' I am the person who dares to publish your annotations, and send you your own work. If you are not pleased with it, it may be all very well; it is sufficient that you please us. If I have done wrong, you are to blame: Why did you not publish it yourself? I threaten you farther, to steal and publish your remarks upon Genesis, the Gospels of Matthew and John, unless you supersede me by bringing them forward."

In the course of the dispute between Luther and Erasmus, the latter made several artful attempts to draw Melancthon from the cause of the reformers, by the prospect of promotion from the popish party. The reply of Luther's friend sufficiently showed that his moderation and mildness were very different from timidity or indifference: "For my part I cannot, with a safe conscience, condemn the sentiments of Luther, however I may be charged with folly or superstition—that does not weigh with me. But I would oppose them strenuously, if the scriptures were on the other side. Most certainly I shall never change my sentiments from a regard to human authority, or from the dread of disgrace." In the year 1525, he repaired to Nuremberg, on the express solicitation of the senate, to assist in planning the establishment of a public seminary in that place, and afterwards delivered an oration at the opening of the academy, but declined the offer of one of its professorships. Amidst all his public and private engagements, which he mentions in his letters as at once oppressive to his mind and injurious to his health, he found means to publish a variety of useful compositions; among which were introductions to several of the sacred books, a Latin version of the Proverbs of Solomon, and an Epitome of the Doctrines believed and taught in the Reformed Churches.

He was employed by the Elector of Saxony to draw up in the German language a memorial on the side of the reformers, to be presented to the diet, which met at Spires in 1526; and was regularly consulted by the Landgrave of Hesse on the means of promoting the reformation in his dominions. His pen was employed also in preparing a directory for the churches in Saxony, which was entitled *Libellus Visitatorius*, in which the Papists pretended to discover a difference in sentiment from Luther, because it was expressed in a strain of moderation; while Agricola, a friend of the author, and the founder of the Antinomian heresy, declaimed against its doctrine on the necessity of repentance, and involved him in a painful dispute on the subject. But he was soon called to take part in the still more serious controversy among Protestant divines on the subject of the sacrament; and, while he adhered at first to Luther's notion of consubstantiation, his opinion became gradually more inclined to that of Zuinglius. It was a more important task even than this, to which his whole faculties were required, when he was called to extend the materials furnished by Luther, and to draw up the *Augsburg Confession of Faith;* and though, in the course of the discussions on the various articles at the diet, in which he bore the principal part on the side of the reformers, he was inclined to yield more than Luther approved, in regard to the ecclesiastical jurisdiction of the bishops, (of whose good intentions he hoped too favourably,) yet, in all doctrinal points, he maintained the character of an enlightened and inflexible protestant. In these various conferences, he displayed all the excellence of his character, as well as the abilities of his mind; and all the efforts of the Romanists were exerted, without success, to gain him over to their cause. Amidst all his constitutional softness, the integrity of his principles, and the intrepidity of his mind, were repeatedly manifested; and, when Cardinal Campegius ultimately refused all toleration of the Protestant sentiments, he made this mild but resolute reply, "Well, then, we commend ourselves and our concerns to God. If he be for us, who can be against us? We shall wait with patience whatever may happen to us. If it be necessary, we would (if such be the will of God) rather fight and die, than betray so many souls." In the year 1534, he was commissioned to confer with Bucer at Casel on the sacramentarian controversy; and would most likely have conciliated matters, had Luther been disposed to moderate his violence; but, as it was, he succeeded in greatly abating the hostility of the Saxon reformer to the brethren of Switzerland. In the same year he was engaged in a similar conference with the Romanists at Leipsic, where he equally failed in his object, through the assuming obstinacy of the papists, while he equally manifested the excellence of his own spirit. His name had now attained the highest celebrity throughout the nations of Europe; and he was successively invited, or rather earnestly entreated, both by Francis I. of France, and by Henry VIII. of England, to visit their respective courts; but was prevented, in both cases, by the wishes of the Elector of Saxony, who was afraid of giving offence to Charles V and who probably augured little good from either of the monarchs. They had doubtless their own political views to gratify in the proposal; but it proves the eminence of Melancthon's name, when both these powerful princes were desirous to avail themselves of his influence. Both he and Luther had considerable hopes of inducing the king of England to pursue his apparently favourable disposition towards the cause of the reformation; and Melancthon wrote several letters, besides transmitting some of his publications to Henry, from whom he received in return, a present of 200 crowns, and the highest expressions of approbation of his zeal in the cause of the Christian religion. In consequence, however, of this communication with the English court, he formed an acquaintance with Archbishop Cranmer, to whom he had recommended Alexander Aless, a learned Scotchman, who had been driven from his native country by the violence of the Popish party, and who afterwards acquired great favour with King Henry.

Upon the appointment of a general council to meet at Mantua in May 1537, his services were again required by the Protestant leaders, to devise some common form of doctrine, which might unite the reformed churches; and to select those articles of faith, which from their radical importance, were necessary to be retained and avowed at all hazards in the proposed accommodation with the Catholics. In the prosecution of these objects, he drew up a treatise on the supremacy of the pope and jurisdiction of the bishops, which met with great approbation from the Protestant deputies; and which manifested at once his firmness in what he conceived to be essential principles, and his strong desire of a reconciliation. But many were ready to misinterpret his intention, and to censure his love of peace, while he was resisting offers from the popish princes, which perhaps few of these calumniators would have been able to withstand. In 1539, in the Protestant conference at Francfort, he was deputed to write on the subject of lawful defence; and soon afterwards addressed a letter of strong remonstrance to the wavering and wayward King of England, on his conduct in the cause of the reformation.

To give a full view of the services of this eminent and indefatigable labourer in the cause of revealed religion and of the reformed doctrines, would require us to enter into all the leading events of the age in which he lived. In a conference at Worms in 1541; in aiding the plans of the Elector of Cologne for promoting the reformation in the diocese in 1543; in rendering similar services to the Elector Palatine Frederic in 1545; in preparing for the expected council of Trent a statement of the chief reasons of the Protestant dissent in 1546; in almost every thing, in short, that was to be written—his pen was successively and unremittingly employed. After the death of Luther, with whom he consulted and corresponded on all occasions, he found himself still more unceasingly harassed by the accumulating interests of the reformation, at the most critical period of its progress. Upon the publication of the temporary rule of faith for all parties, called the Interim, (of which the emperor enforced the observance by force of arms,) Melancthon attended seven conferences at Leipsic, and wrote all the pieces which were then presented in the discussion of this imperial creed. The result of these deliberations was the publication of a treatise from his pen, and a decree of the Saxon nobility and clergy, on the observance of things of an indifferent nature. In this work, and the disputes which followed, called the Adiophoristic controversy, Melancthon has been most unjustly accused of having abandoned the truth through excessive timidity and servile compliance; but a few quotations from his published sentiments at the moment, will sufficiently expose the unfounded nature of these aspersions: "Though threatened with war and destruction, we must still adhere to the word of God, and not deny acknowledged truth. As to the danger incurred by the defence of what is preached in our churches, and we know to be truth, we will entrust the affair to God." "Let the potentates and rulers consider, amidst the alarms of war now prevalent, what they will, and what they ought to do in this affair, for the peace of the church. As for myself, I am ready, by the grace of God, to depart hence, and if need be to suffer."—"We have been lately written to, and admonished not to preach, teach, or write against this Interim; but necessity compels us to say this much, with all humility of mind, that we will not alter in what we have hitherto taught in our churches; for no creature possesses power or authority to change the word of God, and it is at every one's peril to deny or forsake the known truth. As, therefore, this Interim is opposed, in many of its articles, to the truth we have advocated, we feel it necessary to publish, in a Christian spirit, an explicit answer: the danger incurred by this measure, we cheerfully face, committing all to the eternal God, the father of our Lord Jesus Christ."

Besides arranging the order of the churches and academies in Misnia, in 1553, and assisting at a conference at Nuremburg, in 1554, for the purpose of consolidating a union between the houses of Saxony, Brandenburg, and Hesse, he was engaged in discussing the subject of the union of two natures in the Saviour, against Osiander and Stancarus, and also in vindicating himself from the clamours and calumnies excited against him by Flacius. In the expectation of being driven into banishment by the intemperate proceedings of his enemies among the more violent of the reformed, he had adopted the resolution of withdrawing to Palestine, and devoting the remainder of his life to the retirement of a hermit, and the composition of works in defence of divine truth. "At the head of all the principal literary and ecclesiastical transactions of the age," says Cox, "consulted by princes, dispatched upon every urgent occasion on different journies, summoned to private conferences and public councils, necessitated to maintain a most extensive correspondence, opposed and even insulted by a violent faction, and watched as a heretic by the partisans of the Roman hierarchy, he represents himself as tormented upon the rack of incessant engagement, and absolutely distracted with writing disputations, regulations, prefaces, and letters." Exhausted at length by his unremitting exertions, by grief for the loss of friends, and by anxiety for the fate of pure religion, he became desirous of a release from his toilsome life; and, after lingering several weeks under the influence of an intermittent fever, he expired on the 19th of April, 1560, in the sixty-third year of his age, in the full possession of his mental faculties, and in the most placid state of pious hope. Upon being asked by one of his friends, in his last moments, if he wished any thing else, he replied, "aliud nihil nisi cœlum," "*nothing else but heaven;*" and requested those who were endeavouring to adjust some parts of his clothing, "not to disturb his delightful repose." The public were allowed to gratify their anxiety to see his body before its interment; and their attachment to his character was singularly manifested, by their picking up every pen, or piece of paper upon which he had written, or any thing that he had used, however insignificant in itself. His remains were placed in a leaden coffin, and deposited close by the body of Luther. We could dwell with much complacency, and at great length, on the delineation of a character, which presents so rare a combination of intellectual and moral endowments; and which, even when it is exhibited to the world, is so seldom estimated as it merits, amidst the violence of human contentions. But it is our proper province to select and abridge the materials of biography, rather than to expand its lessons of instruction; and we must content ourselves with a very rapid sketch of what would well deserve to be placed, in all its most attractive lights, before the exasperated spirits, who crowd the departments of modern controversy.

Philip Melancthon has been invariably numbered among the most illustrious instruments of the reformation; and was by far the most powerful coadjutor, as well as the warmest personal friend of the Saxon reformer. He was peculiarly qualified to supply the deficiencies, and to correct the errors, of his intrepid associate; and it would be a difficult task to decide whether the cause of true religion was more indebted to the zealous spirit of the one, or to the persuasive virtues of the other. Nothing, at least, can be more pleasing, than to contemplate the high opinion which they entertained of each other, and the uniform steadiness of their mutual friendship amidst all the attempts of their enemies to create a disunion. "Though not perfectly *agreed*, they were perfectly *united*," says Cox, and never could be induced to regard each other as rivals. "Pomeranus is a grammarian," said Melancthon, "I am a logician, and Justus Jonas is an orator; but Luther is good at every thing, the wonder of mankind; for whatever he says or writes, it penetrates the heart, and makes a lasting impression." "I am born to be a rough controversialist," said Luther, "I clear the ground, pull up weeds, fill up ditches, and smooth the roads. But to build, to plant, to sow, to water, to adorn the country, belongs to Melancthon."

Melancthon's early talents, extensive learning, and classical acquirements, have been already noticed; but his intellectual acuteness in discriminating between truth and sophistry, was not less distinguished than the elegant perspicuity with which he conveyed his sentiments. He possessed an extraordinary memory, which was greatly aided by the regularity of his habits, and the equanimity of his mind; and was not less remarkable for the facility with which he could recollect his well arranged stores of information. He spared no time or application in the investigation of every important topic; and, in all his researches or discussions, was actuated by the most undeviating love of truth. His own intentions were as upright as his conceptions were clear; and there was a kind of *transparency* (as has been well expressed) in the whole stream both of his arguments and his motives. "I will give you an answer to-morrow," he said on one occasion to Eckius, who had made use of some puzzling sophism in their disputation. "There is no merit or honour in that," said his antagonist, "if you cannot answer me immediately." "Mi doctor," replied Melancthon, with the greatest composure, "non quæro meam gloriam hoc in negotio, sed veritatem: cras, volente Deo, me audies." It was his avowed principle to speak what he thought firmly, but modestly; and to concede what he deemed might be conceded with unambiguous ingenuousness. This was not a spirit likely to please any party in an age of violent contention; and he was incessantly assailed and tormented, through the whole of his life, by the bigotry both of friends and enemies. Yet his dispassionate temper, unbiassed candour, and love of peace, were by no means (as has been often advanced) the consequence of scepticism in principle, insensibility of feeling, or timidity of spirit. The most fiery zealot in the cause of the Reformation never pursued its interests with greater perseverance than he did; nor did he even temporize in those points, which his penetrating mind saw to be essential; and he would have died (as he often avowed) for what he maintained. He possessed also all that acute and excitable feeling, which generally accompanies true genius; and his anxiety for the success of the great cause which he had embraced with all the ardour of enlightened piety, arose often to the degree of absolute hypochondriasm.

His acquisitions of knowledge were made with little exertion; and his unclouded serenity of mind kept his faculties always fit for service. His bodily frame was slender, and his constitution never robust; but his habits were regular, and his mode of living strictly temperate. He retired to rest at an early hour, and usually rose a little after midnight. He estimated time as the most precious of all possessions; and, when he made any appointment, expected it to be kept literally to a minute. His services to general literature were of the highest order, and he had great influence in reviving the study of the ancient writers. He led the way in classical composition among his countrymen; and, though his attempts at versification were far from being successful, he wrote Latin in prose with an ease and purity rarely equalled. Amidst all the avocations in which he was involved, he employed the greater part of every year in giving lectures to 1500 pupils; and, even among the increased infirmities of his last days, he persevered in the labours of his class with an assiduity almost approaching to obstinacy.

But neither his attachment to literature, nor his multifarious engagements in public affairs, could seduce him from the participation of domestic feelings and duties. His attention to his own family was never relaxed amidst his greatest perplexities, and he was occasionally found by his visitors holding a book in one hand, and rocking his child's cradle with the other. He was fond of the society of children in general, to whom he could render himself at once a captivating and instructive companion, joining cheerfully in their sports, and exercising his ingenuity in devising amusements suited to their years. He was much inclined at all times to a jocular strain of conversation; and was so extremely frank in his communications, from the entire purity of his motives, as frequently to expose himself to the artifices of designing men. He was a pattern of sympathy towards his friends; and was distinguished at all times by the most disinterested generosity of disposition, which he often carried to a faulty extreme. The various presents of gold and silver coins, or other curiosities which he frequently received, he would often give away to the first person who might be induced to ask for them; and it is said, that, on one occasion, having offered a stranger any particular article in a large collection which he was showing to him, and the visitant having, with consummate cupidity, expressed a wish for them all, he actually granted the unreasonable request, while he could not conceal his displeasure at such an instance of avaricious effrontery. He was equally profuse in his daily charities; and so completely disinterested, as to decline repeatedly proposed additions to his salary in the university, as well as to refuse the most lucrative offers of promotion, and proffered presents from his princely friends. He was remarkably humble in his whole deportment; and was often known to perform various menial offices for himself. He was invariably animated by a gentle and peaceful spirit, averse from disputation, almost never known to be irritated in the course of debate, and still less to have harboured resentment in consequence of any heat that might have been excited, or hasty expression thrown out. Nor was he, by any means, a tame and feminine character; but, while "he was apt to sink into a kind of yielding softness under the influence of mild and generous treatment, (to use the words of Mosheim,) if his adversaries so far forgot themselves, as to make use of imperious language and menacing terms, then a spirit of intrepidity, wisdom, and independence, animated all his words and actions, and he looked down with contempt on the threats of power, the frowns of fortune, and the fear of death." But his passions were all controlled by the dictates of reason, and especially by the power of fervent yet unobtrusive piety, which was the brightest ornament of his exalted character, and the leading motive of his valuable exertions. The most ample and most correct edition of his works, is that which was published by his son-in-law, Caspar Peucer, at Wittemberg, in 1601, in four volumes folio. See Mosheim's *Eccles. Hist.* vol. iv. ; Melchior Adam *Vitæ Germ. Theologorum* ; Seckendorf *Hist. Lutheranismi* ; Bayle's *Critical Dictionary* ; Camerarii *Vita Melancthonis* ; Cox's *Life of Melancthon* ; Milner's *Church History*, vol. iv. and v. (*q*.)

MELCOMBE-REGIS. See Weymouth.

MELKSHAM, a village of England, in the county of Wilts, consists chiefly of one long street, of which the houses are built of a soft free-stone. It contains a parish church, and three meeting-houses for Quakers, Independents, and Baptists. It carries on the manufactures of broad cloths. Number of houses 785. Population 4030.

MELLITIC Acid. See Chemistry.

MELODY, in Music, such a pleasing *succession* of musical sounds, as was by the earliest writers on music called Harmony, (see that article,) a term which now is exclusively applied to denote the pleasing effects of a proper selection of sounds *heard together* at the same time. In correct performances by a choir of good voices, or by a band of Perfect *Instruments*, making *Perfect* Harmony, (see these articles,) such as violins, violoncellos, &c. or a Listonian or Enharmonic *Organ*, are capable of producing, when skilfully played, a considerable number of the leaps or steps of the melody in such performances are necessarily tempered, or made a small quantity larger or smaller, than that exact quantity which each of such steps or intervals must have when introduced in harmony ; that is, when the limiting sounds of such intervals are heard together at the same instant. A nice and well practised ear for music, will doubtless perceive *the temperament of the melody* of which we are speaking, and can hardly fail, on first hearing and considering them, during an enharmonic performance, to consider them as defects, and wish for their being avoided. Every attempt, however, to do so, by removing the temperaments from the melody to the harmony, is accompanied by so much interruption and debasement from *the beats*, by which such tempered harmonies are accompanied, as to produce conviction that the harmony ought, in all instances, to be kept perfect ; and the temperaments, by which unavoidably all music in parts is attended, must be thrown entirely into the leaps of the melody, where no beats or beatings will be found to accompany their use. See this subject further discussed in the *Philosophical Magazine*, vol. xxvii. p. 314. (*e*)

MELOS. See Milo.

MELROSE, a town and parish in the county of Roxburgh, extending in length from north to south about seven miles and in breadth from five to seven miles. The population is about 2446.

The soil of this parish is various. Towards the south, it is for the most part a strong clay, excellently adapted for wheat. The banks of the Tweed, which winds through the parish, consist of a fine light dry soil, fit for all kinds of grain. On the north side of the river, the soil is of three kinds: 1st, A light earth, mixed with sand, upon a gravelly bottom ; 2d, A strong clay upon a till, full of springs, and very wet; and 3d, Moss. The northern part of the parish is hilly, and makes excellent sheep pasture, interspersed with a few small fields under cultivation. The valued rent of the parish is 19,985*l*. 4*s*. 6*d*. Scots.

The town of Melrose, which gives its name to this parish, was formerly a burgh of regality. It is pleasantly situated at the bottom of the Eildon hills, on the north side, and on the edge of a fertile valley, upwards of a mile in length, intersected by the Tweed, which runs through it in a serpentine direction, and surrounded by hills of a considerable height. In this valley, besides Melrose, are the villages of Danieltoun, Darnick, Bridge-end, Gattonside, Newstead, Eildon, Newtown, and Blainslie.

Melrose was long celebrated for its manufacture of linens ; but for several years past this trade has been very much upon the decline. The business of bleaching linens is carried on to a considerable extent; and the woollen manufacture has, of late, been cultivated with success.

A little to the south of Melrose, are the three Eildon hills. The base of them may be in compass six or seven miles ; the heighth of two of them to the north about a mile and a half. On the top of the north-east hill are plain vestiges of a Roman camp, well fortified with two fosses and mounds of earth more than a mile and a half in circuit, with a large plain near the top of the hill, on which may be seen the *prætorium*, or the general's quarter, surrounded with many huts. The situation seems to have been skilfully selected, and it has all the properties of a well chosen camp, according to the rules of Vegetius. There is a large prospect from it of all the country ; it has many springs of good water near it ; the sides of the hill have been covered with wood ; and the camp is so extensive, that neither man, beast, nor baggage, could be straitened for room. On the north side of the middle hill, there seems to have been a second camp, from which there is a large ditch for two miles to the west, reaching to another camp on the top of Caldshielhill. This camp has been strongly fortified with a double trench, and the circumvallation of it continued for a considerable way ; and, along with the camp called Castlestead, it forms almost a triangle with the large camp in Eildon hills. The vestiges of two other large camps are also found in this neighbourhood ; the one on the head of the hill, on the side of which the village of Gattonside is founded, north of the Tweed, which is surrounded by a wall of stone about half a mile in compass ; the other about half a mile to the east, on the top of the hill opposite to Newstead, which seems to have been about three quarters of a mile in circumference, and is called the *Chester Know*, or *Knoll*. The eastern Roman military road is visible in many quarters of this country, raised in some places considerably above the adjoining fields, and of a considerable breadth, with military stations on some parts of it.

But the most remarkable monument of antiquity to be found in this quarter, is the abbey of Melrose. Various religious foundations, of different dates, appear to have existed at this place. The ancient monastery of Old Melrose, situated on a little peninsula formed by the windings of the Tweed, was probably founded about the end of the sixth century. The venerable Bede, who was born in 673, gives an account of its situation on the bank of the Tweed, and also of its abbots. It was a famous nursery for learned and religious men, and probably continued until the other one, at the present Melrose, was founded by King David. The convent of Old Melrose was enclosed with a stone wall, reaching from the south corner to the west corner of the Tweed, where the neck of land is narrow; and the foundation of the wall is still to be seen.

About a mile to the west of this, on the Tweed, stands the village of Newstead, a place remarkable for another abbey on the east side of it, called Red Abbey-stead; and about half a mile from Newstead, on the south side of the river, stands the present abbey of Melrose. This monastery, from the ruins which yet exist, appears to have been truly magnificent and spacious. It still continues to be the admiration of strangers; and from the height and embellishment of its columns, the symmetry of its parts, the beauty of the stone of which it is built, and the delicacy of its sculpture, it may be regarded as one of the finest specimens of Gothic architecture which exist in this country. It was founded by king David in 1136, dedicated to the Virgin Mary, and endowed with large revenues and many immunities, as appears by the charters granted to the abbot and convent by our kings. The monks were Cistertian, and the monastery of Melrose was a mother church or nursery for all that order, in many various and remote regions of Scotland.

The church is built in the form of St. John's cross. The chancel, which is a very stately fabric, is still standing; its roof is very curious, and has much of the scripture history sculptured upon it. Much of the western part of this building is so entirely demolished, that it cannot be precisely ascertained how far it reached in that direction. What still exists is of the following dimensions. Its length is 258 feet, breadth 137½, circumference about 943; height of the east window 24, breadth 16; height of the south window 34½, breadth 15½; height of the steeple 75, the spire gone. The east window, at which was the great altar, is a beautiful structure, consisting of four pillars or bars, with a great deal of curious work between them; and on each side a great number of niches for statues; on the top, an old man with a globe in his left hand, resting on his knee, and a young man on his right, both in a sitting posture, with an open crown over their heads. (See Plate CLXX. of Civil Architecture.) On the north and south of this window are two others of smaller dimensions. The niches are curiously carved, both the pedestals and canopies, on which several figures of men and animals are curiously cut. On the south-east of this church are a great many musicians, admirably cut, with much pleasantness and gaiety in their countenances, accompanied with their various instruments; also nuns with their veils, some of them richly dressed. The south window is very much admired for its height and curious workmanship. There are niches on each side and above it, where have been statues of our Saviour and the apostles. Besides, there are many other figures on the east, or on the west side of this window: monks curiously cut, with their beards, cowls, and beads; a cripple on the back of a blind man; several animals cut very nicely, as boars, greyhounds, lions, monkeys, and others. There are about sixty-eight niches in the whole, standing; the statues were only demolished about the year 1649.

With regard to the inside of the church, on the north side of the cross, there are beautiful pillars, the sculpture as fresh as if it had been newly cut. On the west side is a statue of St. Peter; and to the south of it one of St. Paul. In the middle of the cross stood the steeple, a piece of noble architecture; a quarter of it yet standing, but the spire gone. The roof of the south side of the cross is still standing, where there is a beautiful stair-case, much admired, the roof of it winding like a snail-cap. There was within the church a vast number of fonts, curiously carved, and altars dedicated to various saints. In the portion of the church where worship is at present performed, there are two rows of pillars of excellent workmanship, especially that to the south-east, which, for fineness, looks like Flanders lace.

With regard, lastly, to what was in part or altogether separated from the body of the church, there was a cloister on the north side, a part of the walls of which are still remaining; and where may be observed pleasant walks and seats, with a great many fine flowers of various kinds, nicely cut. The door at the north entry of the church is curiously embossed; and the foliage here, and in several places of the church, very beautiful. There were also here a great many fine buildings within the convent, for the use of the abbot and monks, with gardens and other conveniences; all inclosed within an high wall, about a mile in circuit. Besides the high church, there has been a large fine chapel where the manse now stands; and another house adjoining to it, where the foundation of the pillars is still to be seen. On the north side of this house, there has been a curious oratory, or private chapel, the foundation of which has been lately discovered, and a large cistern of one stone, with a leaden pipe, conveying the water to it. See *The Statist. Account of Scotland*, vol. ix.; Forsyth's *Beauties of Scotland*, vol. ii.; and the *Description of the Parish of Melrose*, by the Rev. Mr. Milne, 1743. (z)

MELTON MOUBRAY, a market town of England, in Leicestershire, is situated in a vale on the banks of the river Eye, over which there are two good bridges. The Oakham canal, which is also crossed by a good bridge, runs behind the principal street. The town consists of four streets, in the form of a cross, and has many well-built houses. The church, which is very large, consists of a nave, aisles, transept, and chancel, with a high and elegant tower in the centre. There is here a free-school for girls, and three annual fairs. The population of the parish in 1811 was 411 inhabited houses, and 2141 inhabitants.

MELVILLE, Andrew, a learned Scotsman, and one of the most distinguished successors of John Knox in the Prysbyterian church, was the youngest of nine sons of Richard Melville of Baldovy, in Forfarshire, and was born on the 1st of August, 1545. In his second year, he lost his father at the battle of Pinkie, and was brought up in the family of his eldest brother Richard, where he was treated with great tenderness and affection. While a child, he was distinguished as much for the quickness of his capacity, as for the delicacy of his constitution; and his brother resolved to give him as complete an education as the age could afford. He was instructed in grammar by Thomas Anderson, then schoolmaster, and afterwards minister, at Montrose, who also initiated him into the principles of the reformation; and after having completed the usual routine of elementary education at the Latin school, he studied the Greek and French languages under Pierre de Marsilliers, a Frenchman, who was then engaged in teaching at Montrose. In 1559, he became a student in St. Mary's College, St. Andrews; and after completing his academical course there, he sailed to France in his nineteenth year, and engaged ardently in the study of letters and philosophy in the university of Paris. For the purpose of studying the civil law, he repaired to Poitiers in his twenty-first year; and, on his arrival, he was made a regent in the college of St. Marceon. Here he continued three years, prosecuting with great success the study of jurisprudence, and at the same time distinguishing himself as a teacher of rhetoric. His next object was to study theology, and with this intention he went to Geneva, where he immediately proved himself worthy to fill the vacant chair of humanity.

In the year 1574, at the urgent desire of his friends in Scotland, Melville resigned his office at Geneva, and returned to his native country. Some of his friends now endeavoured to persuade him to accept the appointment of domestic instructor to the Regent Morton; but this he declined, and spent a few months in his elder brother's house, assisting the studies of his nephew, James Melville, who had recently completed the usual course of academical education at St. Andrew's. Soon afterwards, at the solicitation of Archbishop Boyd, and other leading men in the west, he accepted the office of Principal of Glasgow college, and carried his nephew James along with him to act as regent. In this situation he laboured with great diligence and success, introduced a new plan of study, and made many useful improvements in the mode of teaching; and a new foundation, which was given to the college at this time by royal charter, ratified all the dispositions which Melville had made for the advancement of learning. Among his other services to the university, he deserves the credit of having founded the public library, though it does not appear that he enriched it with any donations from his own collection. About this time, he first became known as an author, by the appearance of his poetical translation of the Song of Moses, &c. printed at Basil, in 1574,—a collection which experienced a most flattering reception from all the men of learning and taste in Europe.

The constitution of his office, as a professor of divinity, entitled him to a seat in the ecclesiastical judicatories; and he took a very active interest in the public affairs of the church. When he arrived in Scotland, an incongruous species of church government,—nominally Episcopalian, but which neither satisfied Episcopalians nor Presbyterians,—had been introduced; but Melville was convinced that prelacy is not founded on the authority of Scripture, or on the practice of apostolical times; and having conceived a partiality for Presbyterian parity, in consequence of his experience of its good effects in Geneva, he determined to exert himself to establish the same model in his own country. In the month of March, 1575, he was first a member of the General Assembly; and his name was included in a committee appointed to confer with the government on the subject of the polity of the church, and to prepare a scheme of ecclesiastical administration, to be submitted to a future Assembly. In the year 1578, the second book of Discipline was approved by a General Assembly, in which Melville presided; and from that period it has been the standard of Presbyterian church government.

But the General Assembly, in their zeal to reform the government of the church, were not inattentive to the means of improving the seminaries of education. At the suggestion of Melville, in conjunction with Arbuthnot and Smeton, plans were formed for amending the constitutions of the universities of St Andrew's, Glasgow, and Aberdeen, on a principle similar to that which had been recommended by the reformers in the first book of Discipline. A favourite project with Melville was, to transform one of the three colleges of St. Andrew's into a school of divinity; and, through his influence with the government and the church, the design was accomplished in the year 1579. Melville himself was placed at the head of the new theological seminary, by the voice of his country; and for more than twenty years the success of the institution exceeded the most sanguine expectations.

Melville began to discharge the duties of principal and professor of divinity in the new college of St. Andrew's, in December, 1580, with the assistance of his nephew James, as professor of the oriental languages, and John Robertson, as professor of the New Testament. His class was crowded with auditors, consisting not only of students of theology, but of masters in the other colleges; all of whom acknowledged the singular ability with which he accomplished his arduous undertaking. Melville, however, with all his excellencies, appears to have been passionately fond of innovation; and to a rational discernment of the defects of the Aristotelian philosophy, he added an undue admiration of the writings of Ramus, whose lectures he had attended in his youth, and whose spirit he had freely imbibed. The Peripatetic prejudices of the professors in St. Salvator's and St. Leonard's college were roused to fury by the attacks upon their favourite author; and, for some time, their indignation could scarcely be appeased. Yet such was the address and superior intelligence of the principal, that he not only disarmed their animosity, but speedily converted the most obstinate among them to his own peculiar views.

In addition to his academical charge at St. Andrew's, Melville, during the first two or three years of his residence, generally performed divine service, and took a share of the other ministerial duties of the parish. His gratuitous labours were highly gratifying to the inhabitants in general; but the freedom and fidelity with which he reproved vice, exposed him to the resentment of several leading individuals; and the most atrocious calumnies against Melville were conveyed to the king, whose mind was predisposed to receive any insinuation to his disadvantage. He was accordingly summoned to appear before the privy council on a charge of treasonable expressions uttered in one of his sermons; and though he produced the most explicit proofs of his innocence, he was sentenced to imprisonment in the castle of Blackness, for having declined the jurisdiction of the council, and for having conducted himself proudly and contemptuously in their presence. Melville, however, contrived to make his escape to England; whence he returned twenty months afterwards, in company with the banished noblemen, who had been denounced as traitors on account of the affair of Ruthven, and who appeared before the gates of Stirling castle with such a numerous force, that the king was glad to re-admit to his councils the men, who, only two years before, had fled from his vengeance.

After being reinstated in his office at St. Andrew's, Melville and his nephew took an active part in the proceedings of the synod of Fife, which terminated in the excommunication of Archbishop Adamson, for having dictated and defended the laws subversive of ecclesiastical discipline. When Adamson was relaxed from censure, and restored to his see, Melville was charged to retire to the north of the Tay, and was not permitted to return to his post, till the college had reluctantly consented to oblige one of the king's menial servants, by renewing a lease, to the great diminution of the rental. Not long afterwards, the king, accompanied by Du Bartas the poet, on a visit to St. Andrew's, had an opportunity of hearing from Melville a most spirited and learned, though extemporaneous refutation of an elaborate lecture by Adamson, in favour of his views of royal prerogative.

In the year 1588, Melville, who had been moderator of the preceding General Assembly, summoned an extraordinary meeting, to concert measures for averting the dangers apprehended from the Spanish armada; and, at his suggestion, a deputation of the ministers, barons and burgesses, waited on his Majesty with the result of their deliberations, proffering their lives and their fortunes in defence of the religion and government of the kingdom. The king was offended with the officious loyalty of his faithful subjects, but was pleased to appoint a committee of the privy council to co-operate with them, in devising means for frustrating the designs of the enemy.

On occasion of the queen's coronation, Melville, who was invited as one of the guests only two days before, pronounced a Latin poem, which was received with so much applause, that the king publicly declared that he and the country had that day received such honour as could never be requited. This poem, entitled *Stephanis Kion*, was printed next day, and was received with the highest expressions of admiration by the first scholars of the age. Lipsius exclaimed, *Revera Andreas Melvinus est serio doctus;* and Scaliger, with far more liberal praise than he was accustomed to render, was not ashamed to say, *nos talia non possumus.*

Soon after the death of Archbishop Adamson, in 1592, an act of parliament was passed, ratifying the government of the church by general assemblies, provincial synods, presbyteries, and kirk sessions, and explaining away, or rescinding the most offensive of the acts of the year 1584. This important statute is considered to this day as the legal foundation of the Presbyterian government; and it was regarded by Melville as an ample reward for his laborious efforts.

A tumult which took place at Edinburgh on the 17th of December, 1596, was seized by the court as a handle for the purpose of effecting a change in the constitution of the church; and Melville's influence with the synod of Fife, and with the leading ministers, was most strenuously exerted to counteract the projected measures. A General Assembly was summoned by the king to meet at Leith; and as it was composed chiefly of ministers from the north, who were studiously infected with prejudices against their southern brethren, the adherents of Melville were left in the minority. The next Assembly at Dundee was not quite so tractable, owing to the presence of Melville. To annihilate, or at least to depress this ascendancy, the king proceeded in person, accompanied by his council, to St. Andrew's, to hold a royal visitation of the university; and there, after searching in vain for matter of accusation against Melville, it was ordained that all professors of theology or philosophy, not being actual pastors, should thenceforth be precluded from sitting in sessions, presbyteries, synods, or assemblies, and from teaching in congregations. Preparation was now made for restoring the order of bishops, and the first approach to this measure, was to induce the commissioners of the General Assembly to solicit that the ministers and elders of the church might be represented in parliament. A statute was accordingly passed, declaring prelacy to be the third estate, and asserting the right of such ministers as should be advanced to the episcopal dignity to the same legislative privileges which had been enjoyed by the former prelates. When the Assembly met at Dundee, the king did not venture to introduce the business, till he had commanded Melville and his colleague Johnstone to retire from the town; and the measure was at last carried by a majority of ten. In a conference at Falkland, Melville, in presence of his majesty, maintained his sentiments with his accustomed fearlessness and vehemence, and the king judged it prudent to refer all the matters which were still intended to be adjusted to an assembly which met at Montrose in March, 1600. Melville appeared as a commissioner from his presbytery, and, though not suffered to take his seat, his counsels and his unconquerable zeal served to animate and confirm the resolution of his brethren; and the assembly was with great difficulty prevailed upon to adopt the scheme of the court, under certain modifications.

Melville was a member of the assembly at Burntisland in May 1601, when the king thought fit to renew his engagements as a covenanter, and made a speech to shew the necessity of revising the translation of the Scriptures. In the course of the following year, his Majesty issued a *lettre de cachet*, charging Melville to confine himself within the walls of the college, because he had used some strong expressions in a discourse at the weekly exercise, condemning the worldly and unfaithful spirit prevalent among the ministers. The purpose of this severity was frustrated by the resolution of the presbytery, to transfer the exercise of the New College, and to employ the Latin tongue as the vehicle of their sentiments. At the accession of James to the throne of England, Melville, who had now obtained the indulgence of going six miles round St. Andrews, wrote three congratulatory poems, which prove at least that harsh usage had not the power of restraining the excursions of his fancy.

In the progress of James to the metropolis of England, the Puritans, who were universally favourable to his title, presented a petition, representing their grievances, and praying that the corruptions of the church might be removed. The two universities publicly declared their dissatisfaction with this petition, and denounced vengeance against every one who should presume to question any part of the doctrine or discipline of their church. The terms of these declarations were peculiarly offensive to Melville, and provoked from his powerful pen a most caustic satirical poem, well known by the abbreviated title, *Anti-Tami-Cami-Categoria.* Many attempts were made to retort upon the author; but none of them wounded so deeply, or attracted so much notice, as the original poem.

In 1604 and 1605, the activity of Melville and his nephew, in maintaining the rights of the General Assembly, was so displeasing to the sovereign, that a warrant for their imprisonment was sent from London; but the council found reasons for declining to execute it. In 1606, Melville waited on the parliament at Perth, on behalf of his presbytery, and protested against the act restoring Episcopacy in its ancient form, and reviving chapters; but he was never more suffered to make a similar appearance. He received a letter from the king, ordering him to repair to London before the 15th of September, along with seven other eminent ministers, most of them from Fife, to treat of the affairs of the church. Here they maintained an animated controversy in presence of his majesty, attended by a numerous assemblage of the English and Scottish nobility, and other officers of state, as well as dignitaries of the church. On Michaelmas day, they were ordered to attend the royal chapel, which was decorated with great magnificence. Melville, conceiving that the service did not differ materially from that of the church of Rome, imprudently wrote an epigram expressive of his idea, and as an incorrect copy of it was conveyed to the king, the author was summoned to appear before the English privy council; and the proceedings terminated in his being found guilty of *scandalum magnatum*, and committed to the Tower. His office was declared vacant, and one Robert Howdie was appointed his successor.

The first year of his imprisonment was aggravated by wanton severity, and particularly by that refinement of cruelty, which attempted to shackle the faculties of his mind, by depriving him of the means of expressing his thoughts either by writing or oral communication. Through the influence of Sir James Sempill, he was removed, at the end of ten months, to a more healthy and spacious apartment, and was allowed the use of pen, ink, and paper. When the rigour of his confinement was relaxed, he was consulted both by Arminius and his antagonist Lubbertus on their theological disputes. He still continued to refresh his mind by occasional poems; and in two or three letters to his nephew, he reviewed Dr. Downham's sermon on Episcopacy. In 1610, he printed a specimen of poetical translations of the Psalms into Latin verse; and he never wrote a letter to his nephew, without transmitting copies of some of his verses.

After four years imprisonment, Melville, on the intercession of the Duke of Bouillon, was permitted to accept the office of professor of divinity at the Protestant university of Sedan, in France; but the infirmities incident to the age of three score and ten were now gathering round his head, although he continued to write and act with all the force and fire of his youth. In his 74th year, he wrote an epithalamium on the marriage of the Duc de la Tremouille to the daughter of his benefactor Du Bouillon; and he wrote and published, a year or two afterwards, a treatise in opposition to the Articles of Perth. His health, however, which had been broken by his long confinement, was now sadly wasted; and he died in the year 1622, at the age of seventy seven.

Melville possessed strong natural talents, and his mind was enriched with the choicest stores of ancient and modern learning. His ascendancy was owing entirely to his genius and erudition, and not to any of the arts of management and intrigue. His piety was fervent and unaffected; his benevolence enlarged, but unobtrusive; he was ardent in his pursuits, and disinterestedly zealous in the public service. He possessed great independence of spirit, an unyielding boldness in word and action, and amazing readiness and rapidity in debate. In short, his talents, his erudition, and his heroic courage, well qualified him for a Presbyterian leader in the difficult times in which he lived. See Dr. M'Crie's *Life of Andrew Melville*, &c. Edinburgh, 1819. (z)

MEMEL, a town of Eastern Prussia, is traversed by the small river Dange, which enters the Kurische-Haff, and which, being here about 11 feet deep, allows small boats to pass directly to the sea. The town consists of two parts, Alstadt, the old town, and Frederickstadt; and it has also three suburbs, one of which is beyond the Dange. The town is well fortified, and has a German, Lithuanian, and a Calvinist church. Although the harbour of Memel is large, yet it is obstructed by quicksands, which prevent vessels that draw more that 18 feet of water from entering it. The trade of Memel, which is nearly the same as that of Koningsburg, Elbing, and Dantzic, consists of square timber, round timber, oak and fir staves, linseed, skins, hemp and flax, tallow, bristles, wax, feathers, and Lithuanian yarn. Its imports are chiefly articles of colonial produce. The average number of vessels which trade to this port is between 600 and 700, above two-thirds of which are British. In 1800, 574 vessels arrived, and 584 cleared out; of which 353 were British, 128 Russian, 38 Danish, and 26 Swedish. In 1815, 441 vessels arrived, and 429 cleared out. In 1816, 460 vessels arrived, and 439 cleared out. In 1801, there were here 20 great commercial houses. There is held annually at Memel a fair, frequented by the inhabitants of Courland and the Jews of Poland, where nearly 450,000 crowns worth of merchandize are sold. Population about 6000. East Longitude 21° 50′ 20″ and North Lat. 55° 42′ 15″. See Catteau's *Tableau de la Mer Baltique*, vol. ii. p. 304; and Rorsdanz's *European Commerce*, p. 118.

MEMORY. See MNEMONICS.

MEMPHIS is the name of an ancient city of Egypt, which was both large and populous, and celebrated for its magnificent temples and palaces. Dr. Shaw is of opinion that Giseh or Djiza now occupies the scite of Memphis; but there is reason to think, from the testimony of Strabo, Pliny, &c. that it was situated at some distance from Giseh. Savary places it at Menf or Memph, but Dr. Clarke, who agrees with him in his locality of Memphis, says that the name of the village is *Menshee a Dashoo*, which seems to be Pococke's *El Menshieh Dashour*. See *Herodotus*, Lib. ii. Pococke's *Description of the East*, vol. i. p. 49. Savary's *Letters on Egypt*. Hamilton's *Egyptiaca*, chap. xi. and Clarke's *Travels*, vol. iii. p. 128 and 158.

MENELAUS. See GREECE and LACEDEMON.

MENGS, ANTHONY RAPHAEL, a celebrated painter, was born at Ausig in Bohemia, on the 12th of March, 1728. At the age of 12 his father, who was a miniature painter, carried him to Rome, where he remained three years, studying and copying the works of celebrated painters. Upon his return to Dresden, he employed himself in painting portraits in crayons, in consequence of which be became known to the king of Poland, who made him his cabinet painter, and gave him a house and a pension. Mengs now returned to Rome to resume his early studies, and he began to compose his own pictures. Here he married a lady, Margarita

Guazzi, with whom he hoped to establish himself permanently at Rome; but at the end of four years his father forced him to return to Dresden in 1749, and having seized his whole property, turned him from his house. The king of Poland, with the greatest liberality, gave him a house and carriage, doubled his pension, and permitted him again to visit Rome.

Here he copied the School of Athens by Raphael, for the Earl of Northumberland; and, in consequence of the stoppage of his pension, he executed a fresco-ceiling in the church of the Augustines, which obtained him great celebrity.

The king of Naples, who had admired some of Mengs's pictures, sent for him to Madrid when he ascended the Spanish throne, and offered him a salary of 2000 dollars, a house and a carriage. Mengs accepted this splendid offer, and arrived in Spain in October, 1761, where he was received with great kindness.

Having fallen into a decline, he obtained permission to return to Rome for the benefit of his health. Here he regained his usual strength, and was employed by Clement XIV. to paint in the Vatican. The king of Spain, however, commanded him to repair to Madrid; but he had scarcely continued in Spain more than two and a half years when his ill-health returned. The king gave him full liberty to return to Rome, with his pension of 3000 scudi, and 1000 more to divide among his daughters.

After he had been some time in Rome, he had the misfortune to lose his wife; and his old complaint having again attacked him, he died in 1779, in the 58th year of his age.

His writings were published after his death by his friend the Chevalier Azara, who states that all the technical part of Winkelman's *History of the Arts* was written by Mengs.

MENSURATION.

Geometrical magnitudes of every kind may be expressed in numbers, by considering how often each contains some unit of its own kind.

A square, the side of which is the lineal unit, serves to measure surfaces; and the number of times a superficies contains its unit, is its *area*.

A cube, of which the base is the superficial unit, or its side the lineal unit, is the unit of solids; and the number of times it is contained in a solid is the *content*, or *solidity*.

Mensuration is the system of rules by which the numeral measures of geometrical magnitudes are found: It may therefore comprehend Plane Trigonometry, although, for reasons of convenience, we propose to treat that subject as a distinct theory.

The smallest lineal unit in common use is an inch, and from this other measures are formed, as in the following Table.

TABLE OF LINEAL MEASURES.

12	Inches	=	1 Foot.
3	Feet	=	1 Yard.
2	Yards	=	1 Fathom.
5½	Yards	=	1 Pole *or* Rod.
40	Poles	=	1 Furlong.
8	Furlongs	=	1 Mile.
3	Miles	=	1 League.
60	Geographical Miles	=	1 Degree.
or 69⅓	English Miles .		

Note.—An inch is supposed equal to 3 barley corns.

4 Poles *or* 66 Feet 100 Links, each 7.92 inches	=	1 English Chain.
100 Links, measuring 74 feet	=	1 Scots Chain.

The measures of France may be converted into those of England, by considering that a French toise = 2.1315 English yards; and a French metre = 39.371 English inches.

TABLE OF SUPERFICIAL MEASURE.

144	Square Inches	=	1 Square Foot.
9	Square Feet	=	1 Square Yard.
30¼	Square Yards	=	1 Square Pole.
40	Square Poles	=	1 Rood.
4	Roods	=	1 Acre.
10	Square Chains *or* 100,000 Square links	=	1 Acre.
640	Acres	=	1 Square Mile.

Note.—The Scots acre is to the English acre as 100.000 to 78,694, or, in smaller numbers, 48 Scots acres = 61 English acres.

TABLE OF SOLID MEASURE.

1728 Cubic Inches	=	1 Cubic Foot.
27 Cubic Feet	=	1 Cubic Yard.

Note.—282	Cubic Inches	=	1 Ale Gallon.
231	do.	=	1 Wine Gallon.
2150.42	do.	=	A Winchester Bushel
105	do.	=	1 Scots Pint.

The Wheat Firlot contains 21¼ Scots Pints.
The Barley Firlot contains 31 Scots Pints.

SECTION I.

MENSURATION OF PLANE FIGURES.

Rectilineal plane figures may be resolved into triangles; therefore the mensuration of their sides and angles may be referred to Plane Trigonometry. The determination of their areas forms the subject of this section.

Problem.

To find the area of a parallelogram.

Case I. When the base and perpendicular are given.

Rule. *Multiply the base by the perpendicular height, the product will be the area.*

Let AB and AD. (Plate CCCLXXII. Fig. 1.) the sides of a rectangle ABCD, be divided into parts, each equal to the lineal unit by which they are measured, and let lines be drawn through the points of division parallel to the sides: These will divide the figure into equal squares, each equal to the superficial unit. And since there will be as many squares in a row in the direction of either side as there are units in that side, and as many rows as there are units in the other side, the whole number of squares, or the area, will be the product of the numbers which express the lineal measures of the sides. For example, if the lineal unit be contained four times in one side, and three times in the other side, the area of the rectangle will be $4 \times 3 = 12$; that is, it will contain the superficial unit 12 times.

Since every parallelogram is equal to a rectangle having the same base and altitude, (See Geometry, Sect. IV. Prop 1.) its area will be the product of the base by the perpendicular height.

Example 1. A rectangular board is 5 feet 6 inches long and 9 inches broad, what is its area?

Here the base is 5 *f.* 6 *in.* = 66 *in.*, and the perpendicular height 9 *in.*: The area = 66 × 9 = 594 *sq. in.* = 4 *sq. f.* 18 *sq. in.* = $4\frac{1}{8}$ *sq. f.* Or, by vulgar fractions, since 5 *f* 6 *in.* = $5\frac{1}{2} = \frac{11}{2}$ *f.* and 9 *in.* = $\frac{9}{12} = \frac{3}{4}$ *f.*, the area = $\frac{11}{2} \times \frac{3}{4} = \frac{33}{8} = 4\frac{1}{8}$ *sq. f.* = 4 *sq. f* 18 *sq. in.* Or else by decimal fractions, since 5 *f.* 6 *in.* = 5 5 *f.* and 9 *in.* = .75 *f.*, the area = 5.5 × .75 = 4.125 *sq. f.* = 4 *sq. f.* 18 *sq. in.*

Ex. 2. Required the area of a square ABCD, (Fig. 2.) whose side AB is $10\frac{1}{2}$ inches.

Here $10\frac{1}{2} \times 10\frac{1}{2} = 10.5 \times 10.5 = 110.25$ square inches is the area.

Ex. 3. Find the area of a parallelogram ABCD, (Fig. 3.) whose length AB = 37 feet, and breadth DE = $5\frac{1}{4}$, or 5.25 feet. Here 37 × 5.25 = 194.25 square feet = 21.583 square yards is the area.

Case II. When the two adjacent sides and the angle they contain are given.

Rule. *Radius is to the product of the sides as the sine of the angle they contain to the area.*

In the parallelogram ABCD, (Fig. 3.) draw the perpendicular DE. Then rad. : sin. A : : AD : DE, (See Trigonometry); but AD : DE : : AB × AD : : AB × DE, (See Geometry, 3d Prop. of 4th Sect.); and by Rule 1, AB × DE is the area, therefore Rad. : Sin. A : : AB × AD : area.

Ex. The sides of a rhomboid are 12 feet 4 inches and 15 feet, and the angle between them is 42° 15′, what is its area?

		Rad.	10.00000
Log.	Ft. In.	Sin. 42° 15′	9.82761
	12 4 =	12.333	1.09107
		15	1.17609
	The area . .	124.38 *sq. feet.*	2.09477

Problem II.

To find the area of a triangle.

Case I. When the base and perpendicular are given.

Rule. *Multiply the base by the perpendicular, and half the product will be the area.* Geo. 6. 4.

Ex. The base of a triangle is 250 yards, and the perpendicular 52 yards 2 feet: Find the area.

Reducing the feet to the fraction of a yard, we have 52 *y.* 2 *f.* = $\frac{158}{3}$ *yards.* The area = $\frac{250 \times 158}{2 \times 3} = 6583\frac{2}{3}$ square yards.

Case II. When the two sides and the included angle of a triangle are given to find the area.

Rule. *Radius is to the sine of the included angle as the product of the sides to twice the area.*

This rule follows immediately from Rule 2. for finding the area of a parallelogram.

Ex. Two sides of a triangle are 14 38 and 12.9 chains, and the included angle is 72° 20′, what is its area?

	Rad.	10.00000
Log.	Sine 72° 20′	9.97902
	14.38	1.15776
	12.9	1.11059
Twice the area	17.675	2.24737

The area, . . { 8.8375 *sq. ch.*
A. R. P. Y.
= 0 3 21 12.1

Case III. When the three sides of a triangle are given to find the area.

Rule *From half the sum of the three sides subtract the sides severally. Multiply the half sum and the three remainders continually together, and the square root of the last product will be the area.*

Let ABC, (Plate CCCLXXII.) be a triangle, produce AB one of its sides, and take BD and B *d* each equal to BC; join CD, and C *d*, and through A draw a line parallel to BC, meeting CD and C *d* produced in E and *e*. The angle AED will be equal to BCD. (Geo. 21.1.) which is equal to the angle BDC, (12.1) or ADE; therefore AE=AD (13.1) In like manner, because the angle A *e d* is equal to the angle BC *d*, (21.1) that is, to B *d* C (12.1) or A *d e*, (41.1), therefore A *e* = AD (13.1.)

From A as a centre, with AD or AE as a radius, describe a circle meeting AC in F and G; and from the same centre, with A *d* or A *e* as a radius, describe another circle meeting AC in *f* and *g*, and take FO = CG.

From this disposition of the lines it is manifest that

CF=AD+AC=AB+BC+AC=perimeter,

CO=2 CA,

F *f*=D *d*=2 BC,

F *g*=F *f*+*f* *g*=2 B *d*+2 *d* A=2 BA.

In order to abridge, let *p* represent half the perimeter, and consequently 2 *p* the whole perimeter; also let *a*, *b*, *c* denote the sides opposite to the angles A, B, C respectively; then it follows that

CF=2 *p*.

CG=FO=CF—CO=2 *p*—2 *b*,

C *f*=CF—F *f*=2 *p*—2 *a*.,

C *g*=CF—F *g*=2 *p*—2 *c*.

Draw BH and B *h* perpendicular to CD and C *d*, and because BD, BC, B *d* are equal, the point C is in the circumference of a circle, of which D *d* is the diameter, therefore CD and C *d* are bisected at H and *h*, (6.2) and the angle DC *d* is a right angle, (19.2) hence the figure CH B *h* is a rectangle, and B *h*=C— = ½ CD, also BH =C*h*=½ C *d*. (26.1.)

Join BE, B e; and because E e is parallel to BC, the triangle BAC is equal to each of the triangles BEC, B e C, (0 4.) But the triangle BEC is equal to $\frac{1}{2}$ EC× BH, (2.4) that is to $\frac{1}{4}$ EC×C d; and in like manner the triangle B e C is equal to $\frac{1}{2}$ e C×B h, that is, to $\frac{1}{4}$ e C × CD; therefore the triangle ABC is equal to $\frac{1}{4}$ EC×C d, and also to $\frac{1}{4}$ e C×CD.

Now since CD : C d : : CE×CD : CE×C d (3.4.)
and also CD : C d : : C e×CD : C e×C d;

therefore CE×CD : CE×C d : : C e× CD : C e ×Cd; that is, because CE × CD = FC × CG, (29.4.) and C e×C d = fC × C g, FC × CG : CE × C d : : C e × CD : f C × C g.

From this proportion, by taking one-fourth of each term, and putting the triangle ABC for its equivalent values $\frac{1}{4}$ CE×C d, and $\frac{1}{4}$ C e×CD, we also have $\frac{1}{2}$ FC× $\frac{1}{2}$ CG : trian. ABC : : trian. ABC : $\frac{1}{2}$ f C × $\frac{1}{2}$ C g

Instead of $\frac{1}{2}$ FC, $\frac{1}{2}$ CG, $\frac{1}{2}$ f C, $\frac{1}{2}$ C g, substitute their values found above, and the proportion becomes

$p \times (p-b)$: trian. ABC : : trian. ABC : $(p-a)$ $(p-c.)$

Hence it appears that *the triangle is a mean proportional between two rectangles, one contained by half the perimeter, and the excess of half the perimeter above one of the sides, and the other contained by the excesses of half the perimeter above the other two sides.*

The rule is got from this theorem, by considering that the mean of three proportionals is the square root of the product of the extremes.

Note.—This rule is particularly well adapted to logarithmic calculation.

Ex. 1. The sides of a triangle are 24, 36, and 48, chains. Find the area.

$$a=24$$
$$b=36$$
$$c=48$$
$$2s=108$$
$$s=54$$
$$s-a=30$$
$$s-b=18$$
$$s-c=6$$

$$s\times(s-a)\times(s-b)\times(s-c)=54\times30\times18\times6=174960,$$

$\sqrt{174960}$=418.282 square chains the area.

Or, by logarithms,

$s=54$	1.73239
$s-a=30$	1 47712
$s-b=18$	1.25527
$s-c=6$	0.77815
	2)5 24293
The area = 418.28 sq. ch.	2.62146

PROBLEM III.

To find the area of a trapezoid.

Note. A trapezoid is a quadrilateral, of which two opposite sides are parallel, but not equal.

Rule. Multiply the sum of the parallel sides by the perpendicular distance between them, and half the product is the area.

In the trapezoid ABCD, (Plate CCCLXXII. Fig. 5.) draw the diagonal AC, and from its extremities draw AE, CF at right angles to the parallel sides DC, AB. The figure is made up of the triangles ACB, CAD; the area of the former is $\frac{1}{2}$ AB×CF, and that of the latter $\frac{1}{2}$ CD×AE, or $\frac{1}{2}$ CD×CF, because AE=CF: therefore the area of the trapezoid is $\frac{1}{2}$ AB×CF+$\frac{1}{2}$ CD×CF = $\frac{1}{2}$ (AB+CD) ×CF.

Ex. Let AB and CD, the parallel sides of a trapezoid, be 7.5 and 12.25 chains respectively, and CF their perpendicular distance 15.4 chains. What is the area?

7.5+12.25=19.75 the sum of the par. sides.

$$\frac{19.75\times15.4}{2}=152.075 \text{ sq. ch.} = 15 \text{ ac. } 33.2 \text{ poles the area.}$$

PROBLEM IV.

To find the area of a trapezium.

Case 1. When a diagonal, and perpendiculars on it, from the opposite angles are given.

Rule. Multiply the diagonal by the sum of the perpendiculars, if they are on opposite sides of the diagonal, or their difference, if they are on the same side, and half the product is the area.

For the trapezium ABCD, (Plate CCCLXXII. Fig. 6.) is the sum of the triangles, ABC, ADC, the areas of which are by Prob. 2. Rule 1.

$$\tfrac{1}{2}\text{ AC}\times\text{BE}+\tfrac{1}{2}\text{ AC}\times\text{DF}=\tfrac{1}{2}\text{ AC}\times(\text{BE}+\text{DF}).$$

In this figure the perpendiculars are on opposite sides of the diagonal; but the truth of the rule may be shewn in the same way when they are on the same side.

Ex. The diagonal of a trapezium is 20 feet, and the perpendiculars on opposite sides of it are 4.2 feet and 3.8 feet; find the area.

4.2+3 8=8 the sum of the perpendiculars.

$$\frac{8\times20}{2}=80 \text{ sq. feet the area.}$$

Case II. When the two diagonals and the angle they make with each other are given.

Rule. Radius is to the sine of the angle contained by the diagonals as their product to double of the area.

The trapezium ABCD, (Plate CCCLXXII. Fig. 7.) is made up of the triangles BEC, CED, DEA, AEB. The doubles of the areas of the two first, by Prob. 2. Case 2. are BE × EC × sin. E and DE × EC × sin. E (supposing rad. = 1,) and twice their sum is BD×EC× sin. E. In like manner, twice the sum of the triangles BEA, AED is BD × AE × sin. E, therefore twice the whole area is

$$\text{BD}\times\text{EC}\times\text{sin. E}+\text{BD}\times\text{AE}\times\text{sin. E}=\text{BD}\times\text{AC}\times\text{sin. E}.$$

Ex. The diagonals of a trapezium are 326.8 and 269.2 feet, and they contain an angle of 54$\frac{1}{2}$°, how many square yards are in the area?

rad	10 0000
sin. 54° 30′	9.91069
269.2	2.43008
326.8	2 51428
twice area 71621.5	4.85505

area 35810.7 sq. feet.

PROBLEM V.

To find the area of a regular polygon.

Note. A polygon is said to be regular when its sides are equal, also its angles.

Rule. Radius is to the tangent of half the angle contained by two adjacent sides of the polygon, as half the side to the radius of the inscribed circle; and the area of the polygon is equal to the rectangle contained by half the perimeter and the radius of the inscribed circle.

From C, (Plate CCCLXXII. Fig. 8.) the centre of the inscribed circle, draw CD perpendicular to the side AB, and join CA. CB. Then CD will be the radius of the circle, and AB will be bisected in D, also the angles at A and B will be bisected by AC and BC.

In the right angled triangle ADC rad. : tan. A : : A D : DC, (Trigonometry); hence the truth of the first part of the rule is evident.

Again, since the polygon is equal to the triangle ACB taken as often as the figure has sides, and this space is manifestly equal to a rectangle contained by CD and $\frac{1}{2}$ AB taken as often as the figure has sides, that is, to CD and half the perimeter of the figure, therefore the area of the polygon is equal to a rectangle contained by CD and half its perimeter.

Ex. Find the area of a hexagon, the side being 20 yards. In this case, half the angle of the polygon is 60°.

Rad.	10.00000
Tan. 60°	10.23856
Half the side, 10	1.00000
Log. of rad. of ins. circle	1.23856
Half per. 60	1.77815
1039.23	3.01671

PROBLEM VI.

To find the area of any rectilineal figure.

RULE. Resolve the figure into triangles and trapezoids, and compute their areas separately; the sum will be the area of the rectilineal figure, as is sufficiently evident.

PROBLEM VII.

To find the diameter and circumference of a circle, the one from the other.

RULE 1. As 7 is to 22, so is the diameter to the circumference nearly.

As 22 is to 7, so is the circumference to the diameter nearly.

RULE 2. As 113 is to 355, so is the diameter to the circumference nearly.

As 355 is to 113, so is the circumference to the diameter nearly.

RULE 3. Multiply the diameter by 3.1416, the product is the circumference nearly.

Divide the circumference by 3.1416, the quotient is the diameter nearly.

The truth of these rules will appear from Prop. 10. of Sect. V. GEOMETRY.

Ex. 1. The diameter of a circle is 12 feet, what is its circumference?

By rule 1st, $7 : 22 : : 12 : \frac{12 \times 22}{7} = 37.71$ feet nearly, the circumference.

By rule 3d, $3.1416 \times 12 = 37.6992$, nearer to the truth.

By rule 2d, $113 : 355 : : 12 : \frac{12 \times 355}{113} = 37.699115$, still nearer.

Ex. 2. The circumference of a circle is one pole, or $5\frac{1}{2}$ yards, what is its diameter?

$$\frac{5.5}{3.1416} = 1.757 \text{ yards. The diameter.}$$

PROBLEM VIII.

To find the length of any arc of a circle.

RULE 1. Find the number of degrees in the arc; then as 180° is to that number, so is 3.1416 times the radius to the length of the arc.

By Prob. 7.—3.1416 times the radius is half the circumference, which is an arc of 180°; and the arcs of a circle have the same ratio as their measures expressed in degrees.

Ex. Required the length of the arc ADB, (Plate CCCLXII. Fig. 9.) whose chord AB is 6, the radius being 9?

From C, the centre, draw CD, bisecting the arc; this line will be perpendicular to the chord, and will bisect it. (GEO. 6. 2.)

By Trigonometry. CA = 9 Ar. Comp.	9.04576
is to AP = 3	0.47712
as rad.	10.00000
To sin. ACP = 19° 28$\frac{1}{3}$′	9.52288
Hence ACB = 38° 56$\frac{2}{3}$′ =	38.944

Again,

$$180 : 38.944 : : 3.1416 \times 9 : \frac{38.944 \times 3.1416 \times 9}{180} = 6.117 = ADB.$$

RULE II. A near approximation to any arc of a circle may be found by this proportion,

$$9\ rad. + 6\ cos.\ a. : 14\ rad. + cos.\ a. : : sin.\ a. : arc.\ a.$$

This approximation was investigated as follows:

Supposing the radius of the circle to be unity, let us assume the equation,

$$A \text{ sin. } a + B \text{ sin. } 2a = a(C + D \text{ cos. } a),$$

in which A, B, C, D are numbers to be presently determined, and as we are seeking only an approximation to the arc, let us suppose it to be such a fraction of the radius that its 7th and higher powers may be neglected. Then by well known expressions for the sine and cosine of an arc. See ARITHMETIC OF SINES, § 29.

$$\left.\begin{aligned} \text{Sin. } a &= a - \frac{a^3}{6} + \frac{a^5}{120} \\ \text{Sin. } 2a &= 2a - \frac{8a^3}{6} + \frac{32a^5}{120} \\ a \text{ Cos. } a &= a - \frac{a^3}{2} + \frac{a^5}{24} \end{aligned}\right\} \text{nearly.}$$

Let these values of sin. a, sin. 2 a, and a cos. a, be substituted in the assumed equation, and then, by making the co-efficients of like powers of a equal to each other, we find

$$A + 2B = C + D, A + 8B = 3D, A + 32B = 5D;$$

$$\text{and hence } A = \frac{7D}{3}, B = \frac{D}{12}, C = \frac{3D}{2}.$$

These values of A, B, C being substituted in the assumed equation, and 2 Sin. a Cos. a put instead of Sin. 2a, we have

$$\text{Sin. } a\ (14 + \text{cos. } a) = a\ (9 + 6 \text{ cos. } a).$$

Hence the truth of the rule is evident.

Taking the same example as in last problem, we have rad. $=9$, and sin. $\frac{1}{2}a=3$; hence cos. $\frac{1}{2}a=\sqrt{}$ rad. ^{2} — sin.$^2\frac{1}{2}a)=\sqrt{72}=8.48528$, and we have by the rule $131.91168 : 134.48528 :: 3 : \frac{134.48528 \times 3}{131.91168} = 3.05853 = \frac{1}{2}a$.

Hence the length of the arc is 6.11706; this value is true to the last figure.

Note. For another approximate value to an arc of a circle, see Geometry, Prop. II. Sect. 5. Part 1.

Problem IX.

To find the area of a circle.

Rule 1. Multiply the radius by half the circumference, the product is the area.

Note. This rule also applies to a sector of a circle.

Rule 2. Multiply the square of the diameter by the number .7854, the product is the area.

The first rule has been demonstrated in Geometry, Prop. VII. Sect. 5. Part I.

If the diameter be supposed $=1$, the circumference will be 3.1415927 (10.5), and the area,

$=\frac{1}{2}$ diam. $\times \frac{1}{2}$ circum. $=.7853982=.7854$ nearly.

And since (8.5) circles are as the squares of their diameters, 1×1, or 1, will be to the square of the diameter of any circle as .7854 to the diameter of that circle: Hence Rule 2. is formed.

Ex. Find the area of a circle whose diameter is 12 feet.

In this case half the circumference is $3.1416 \times 6 = 18.8496$ feet, and the area, by rule 1,

$18.8496 \times 6 = 113.0976$ sq. feet the answer.

Or, by Rule 2, the area is $.7854 \times 144 = 113.0976$ sq. feet.

Problem X.

To find the area of any sector of a circle.

Rule I. Multiply the radius, or half the diameter, by half the arc of the sector, and the product will be the area, as in the whole circle.

Rule II. As 360° is to the degrees in the arc of the sector, so is the area of the whole circle to the area of the sector.

The first of these rules is contained in the last problem, and the truth of the second is sufficiently evident.

Ex. Required the area of a sector CADB, (Fig. 9) the angle ACB at the centre being 18°, and the diameter three feet.

By Prob. 7, $3.1416 \times 3 = 9.4248$ the whole circumference; and by Prob. 8, 360 : 18 :: 9.4248 :: 47124 the arc of sector: Hence, by Rule 1, $.47124 \times .75 = .35343$, the area of the sector. Otherwise, by Prob. 9, the area of the circle $= .7854 \times 9 = 7.0686$; and by Rule 2, 360 : 18 :: 7.0686 : .35343, the area of the sector.

Problem XI.

To find the area of the segment of a circle.

Rule. Find by the last problem the area of the sector having the same arc as the segment, also the area contained by the chord of the arc, and the two radii of the sector, their sum, or difference, according as the segment is greater or less than a semicircle, will be the area of the sector.

The reason of this rule is sufficiently evident.

Ex. Find the area of the segment ADB, Fig. 9. which is less than a semicircle, its chord AB being 12, and the radius AC or BC 10.

By Trig. AC : AP :: rad. : sin. ACP $=36° 52'.2 = 36° 87$, the degrees in the Angle ACD; and their double, $73.74 =$ the degrees in the arc ACB. Now, $.7854 \times 400 = 314.16$. the area of the whole circle: Therefore 360° : 36° 87 :: 314.16 : 64.3504 = area of the sector CADB. Again, the three sides of the triangle ACB being 10, 10, and 12; its area (Prob. 2, Rule 3.) will be $\sqrt{(16 \times 6 \times 6 \times 4)} = 48$. Therefore the area of the segment $= 64.3504 - 48 = 16.3504$.

Problem XII.

To find the area of any segment of a Parabola.

Rule. Multiply the base of the segment by its height, and take $\frac{2}{3}$ of the product for the area.

The truth of this rule is proved in Conic Sections, Sect. 7. Prop. 1.

Ex. The base AB, (Plate CCCLXXII. Fig. 10.) of a parabolic segment ACB is 10, and its altitude CD is 6. Hence, by the rule,

The area $= \frac{2}{3} \times 18 \times 6 = 40$.

Problem XIII.

To find the area of an ellipse.

Rule. Multiply the product of the two axes by the number .7854 for the area.

Let a denote the transverse axis AB, (Fig. 11.) and b the conjugate axis CD; the area of a circle that has a for its diameter is $.7854\,a^2$ (Prob. 9.) And a is to b as the area of this circle to the area of the ellipse, (Conic Sections, Sect. VII. Prop. 3.) that is,

$a : b :: .7854\,a^2$: area of ellipse.

Hence area of ellipse $= .7854\,a\,b$.

Ex. The area of an ellipse, whose axes are 10 and 8 feet, is required.

$10 \times 8 \times .7854 = 62.832$ *sq. feet.*

Note. 1. Rules for computing the areas of elliptic and hyperbolic sectors may be derived from the investigations given in Conic Sections, Sect. VII. Prop. 3, 4, and 5.

Note 2. Rules for hyperbolic areas are also investigated in Fluxions, Art. 150.

Problem XIV.

To find nearly the area of a figure bounded by a straight line BQ, two straight lines BA, QP perpendicular to BQ, and any curve line A $a\,a'\,a''$ . . . . P.

Rule. Let BQ, (Plate CCCLXXII. Fig. 12.) the base of the figure, be divided into any number of equal parts by the perpendiculars $b\,a$, $b'\,a'$, $b''\,a''$, &c. which meet the curve in $a\,a'\,a''$, &c.

Let F denote the first perpendicular.

L . . . . the last.

E . . . { the sum of the remaining even perpendiculars, viz. $a\,b$, $a''\,b''$, &c. the 2d, the 4th, &c.

O . . . { the sum of the remaining odd perpendiculars, viz. $a'\,b'$, $a'''\,b'''$, &c. the 3d, the 5th, &c.

D . . . . the common distance between the perpendiculars.

The area of the figure will be nearly equal to

$$\tfrac{1}{3}\,\mathrm{D} \times (\mathrm{F} + \mathrm{L} + 4\,\mathrm{E} + 2\,\mathrm{O}).$$

And the approximation will be so much the more accurate, according as the number of the perpendiculars is the greater.

To prove this rule, join the tops of the first and third perpendiculars by the line A a, meeting the second perpendicular in E, and through a draw CD parallel to A a', meeting AB and $a'\,b'$ in C and D. The space bounded by the curve A $a\,a'$, and the straight lines AB, B b', $b'\,a'$ is made up of the trapezoid AB $b'a'$ and the space contained by the arc A $a\,a'$, and its chord A a'; now, if the arc be small, it may be considered as a parabolic arc, and then the curvilineal space between the arc and its chord will be $\frac{2}{3}$ of the parallelogram ACD a' (Conic Sections, Sect. vii. Prop. I.) Therefore the space A $a\,a'b'$ B will be nearly the sum of the trapezoid AB $b'a'$, and $\frac{2}{3}$ of the parallelogram ACD a'; that is, the sum of $\frac{1}{3}$ of the trapezoid AB $b'\,a'$, and $\frac{2}{3}$ of the trapezoid CBb'D.

Now, Trap. AB $b'\,a'$ = (AB + $a'b'$) B b (Geom. Part I. Sect. 4. Prop. 7.)

And Trap. CB b' D = (CB+D b') B b = 2 $a\,b$ × B b;

Therefore the area of the space A $a\,a'\,b'$ B is nearly

$$= \left\{\tfrac{1}{3}(\mathrm{AB} + a'b') + \tfrac{4}{3}\,a\,b\right\}\ \mathrm{B}\,b$$

$$= \tfrac{1}{3}\,(\mathrm{AB} + 4\,a\,b + a'b')\ \mathrm{B}\,b.$$

In like manner, it may be shewn that the space $a'b'b'''\,a'''$ is nearly

$$= \tfrac{1}{3}\,(a'b' + 4a''b'' + a'''b''')\ \mathrm{B}\,b,$$

and that the space $a'''b'''$ PQ

$$= \tfrac{1}{3}\,(a'''b''' + 4a^{\mathrm{iv}}\,b^{\mathrm{iv}} + \mathrm{PQ})\ \mathrm{B}\,b,$$

and so on; hence the area of the whole figure, which is made up of these, is

$$\tfrac{1}{3}\,\mathrm{B}\,b \times \left\{\begin{array}{l}\mathrm{AB} + \mathrm{PQ} \\ + 4\,(a\,b + a''\,b'' + a^{\mathrm{iv}}\,b^{\mathrm{iv}}) \\ + 2\,(a'\,b' + a'''\,b''')\end{array}\right\}$$

as was to be demonstrated

Ex To find the area of the space ABC, (Plate CCCLXXII, Fig. 13) supposing it to be a quadrant of a circle, the radius of which is = 1.

Let the sector BCE be one-third of the quadrant, draw ED perpendicular to AC, then CD=cos. 30°=½ CA. Divide CD into four equal parts, and draw the perpendiculars $r\,s$, $p\,q$, $m\,n$.

Because CA=1, therefore CD=½, C r=$\frac{3}{8}$, C p=¼, Cm=$\frac{1}{8}$; hence DE=$\sqrt{(1-\frac{1}{4})}$=$\frac{1}{2}\sqrt{3}$, and in like manner, $r\,s$=$\frac{1}{8}\sqrt{55}$, $p\,q$=$\frac{1}{4}\sqrt{15}$, $m\,n$=$\frac{1}{8}\sqrt{63}$. Therefore,

F+L=1+½ √3	=1 8660
4 E=½√55+½√63	=7.6767
2 O=½√15	=1.9365
The sum - -	=11.4792
Multiply by ⅓ D	= $\frac{1}{24}$
The product	= .4783
Subtract the triangle CDE	= .2165
The sector CEB	= .2618
The triple of which is the quad. ABC	= .7854

SECTION II.

MENSURATION OF SOLIDS.

Problem I.

To find the surface of a right prism or cylinder, (Plate CCCLXXII. Fig. 14, 15.)

Rule. Multiply the perimeter of the end by the length or height of the solid, and the product will be the surface of all its sides. To this, when the whole surface of the prism is required, the areas of the ends must be added.

If the plane surfaces which form the sides of an upright prism were extended into one plane, it is manifest, that the surface thus formed would be a rectangle, having one of its sides equal to the height of the prism, and its other side equal to the perimeter of the end; Hence, the truth of the rule is manifest in the case of any right prism. A cylinder may be regarded as the limit of all prisms which can be inscribed in, or circumscribed about its base, therefore, its surface will be the limit of their surfaces; now, the expression for the limit is evidently the product of the circular base by the height.

Ex. 1. How many square yards are in the surface of the walls of a room of any prismatic form, whose height is 10 feet, and circumference 58 feet?

10 × 58 = 580 sq feet = 64$\frac{4}{9}$ sq. yards the answer.

Ex. 2. What is the convex surface of a cylindrical pillar 12 feet long and one foot in diameter?

The circumference of the base, is 3.1416 feet. (Prob. 7. Sect. 1.) And the surface of the pillar 3.1416 × 12 = 37.6992 sq. feet.

Problem II.

To find the surface of a right pyramid or cone. (Plate CCCLXXII, Fig. 16, 17.)

Rule. Multiply the circumference of the base by the slant height, and half the product will be the surface of the sides; to which the area of the end may be added when the whole surface is required.

The truth of the rule will be evident, if it be considered that the faces of the pyramid are equal triangles, having the slant side of the pyramid for their altitude, and that a cone may be considered as a pyramid having an infinite number of sides.

Ex. 1. The slant height of a triangular pyramid ABCD is 20 feet, and each side of the base 3 feet. What is its upper surface?

$$\frac{3 \times 3 \times 20}{2} = 90 \text{ feet the surface.}$$

Ex. 2. Required the convex surface of a cone, the slant height being 5 feet, and the diameter of the base 3 feet.

3 × 3.1416 = 9 4248 the circumference,

½ × 9.4248 × 5 = 23.562 sq. feet the surface.

Problem III.

To find the surface of the frustum of a right pyramid or cone, that is the lower part, when the top is cut off by a plane parallel to the base. (Plate CCCLXXII, Fig. 18.)

Rule. Add together the perimeters of the two ends, and multiply the sum by the slant height, and take half the product for the surface.

For the surface is equivalent to a trapezoid, whose parallel sides are the perimeters of the ends, and height is the slant surface.

Ex. Find the surface of AG, the frustum of a square pyramid, the slant height KE being 10 feet; each side of the greater end AC 3 feet 4 inches, and each side of the lesser end EG 2 feet 2 inches.

Here $3\frac{1}{3} \times 4 = 13\frac{1}{3}$ the perim. of greater end.

$2\frac{1}{6} \times 4 = 8\frac{2}{3}$ the perim. of lesser end.

Their sum = 22 feet.

And $\frac{22 \times 10}{2} = 110$ feet the answer.

Problem IV.

To find the solid content of any prism or cylinder.—(Plate CCCLXXII, Fig. 14, 15.)

Rule. Multiply the area of the base or end by the perpendicular height, and the product will be the solid content.

This rule follows from Geom. Part 2. Sect. 2. Prop. 11. and Sect. 3. Prop. 2.

Ex. 1. The sides of the base of a triangular prism are 3, 4 and 5 feet, and its height is 12 feet: What is its solid content?

By rule 2, of Problem 2. Sect. 1. the area of the base is

$$\sqrt{(6 \times 1 \times 2 \times 3)} = 6 \text{ sq. feet.}$$

Hence the solid content $= 6 \times 12 = 72$ cubic feet.

Ex. 2. The Winchester bushel is a cylinder $18\frac{1}{2}$ inches in diameter, and 8 inches deep: What is its solid content?

The base $= .7854 \times 18.5^2 = 268.803$ sq. inches, Part 1. Prob. 9.

Therefore the solid content $= 268.803 \times 8 = 2150.424$ cubic inches.

Problem V.

To find the solid content of any pyramid or cone.—(Plate CCCLXXII, Fig. 16, 17)

Rule. Multiply the area of the base by the height, and one third of the product is the solid content.

This rule has been proved in Geometry, Part. II. Sect. 2. Prop. 17. and Sect 3. Prop. 3.

Ex. Each side of the base of a triangular pyramid is 3 feet, and its height is 10 feet: What is the solid content?

By Prob 2. of Sect. 1. the area of the base $= 3.89711$ square feet.

Hence $\frac{3.89711 \times 30}{3} = 38.9711$ cubic feet the solid content.

Ex. 2. The diameter of the base of a cone is 8 inches, and its height is a foot. What is its content?

The area of the base $= .7854 \times 8 = 6$ 2832 sq. inches.

And the solid content $= \frac{6\ 2832 \times 12}{3} = 25.1328$ cubic inches.

Problem VI.

To find the solid content of the frustum of a pyramid or cone. (Plate CCCLXXII. Fig. 18.)

Rule. Add into one sum the areas of the two ends and the mean proportional between them, (that is, the square root of their product) and one-third of that sum will be a mean area, which, multiplied by the perpendicular height of the frustum, will give the solid content.

Investigation. Let ABCD be the base of the frustum, EFGH its top, P the vertex of the pyramid, and PM a perpendicular on the base, meeting the top in L.

Let S denote the side of a square equal to the base, s the side of a square equal to the top, put H to denote LM the height of the frustum, and put r for PL the remainder of the perpendicular. By last problem, the content of the whole pyramid is $\frac{1}{3}S^2(H+r)$, and the content of the part above the frustum is $\frac{1}{3}s^2r$, hence the frustum, which is their difference, is

$$\frac{1}{3}S^2(H+r)-\frac{1}{3}s^2r=\frac{1}{3}S_2H+\frac{1}{3}(S^2-s^2)r$$
$$=\frac{1}{3}S^2H+\frac{1}{3}(S+s)(S-s)r$$

Now the base ABCD$=S^2$, and the top EFGH$=s^2$ being similar figures (Geom. Part. II. Sect. 2. Prop. 13.) they are to one another as the squares of their like sides; (Geom. Part. I. Sect. 4. Prop. 27.) that is, $S^2 : s_2 :: AB^2 : EF^2$; hence $S : s :: AB : EF$. But because of the similar triangles PAB, PEF, AB : EF :: AP : EP, and, again, (Part II. Sect. 1. Prop. 12.) AP : EP :: (MP : LP ::) $H+r : r$, therefore, $S : s :: H+r : r$, and $S-s : s :: H : r$, hence, $(S-s)\,r=sH$. This value of $(S-s)\,r$ being substituted in the expression given above for the solidity of the frustum, it becomes

$$\frac{1}{3}S^2(H+\frac{1}{3}(S-s)\,sH=\frac{1}{3}(S^2+Ss+s^2)H.$$

If it be now remarked that the product or rectangle Ss is a mean proportional between S^2 and s^2, the top and bottom of the frustum, it will appear that the formula just found gives the rule.

Ex. The areas of the ends of a frustum of a pyramid or cone are 41.57 and 23.38 square feet, and its height is 9 feet: Find its solid content.

The greater end	=	41.57
The lesser	=	23.38
The mean $=\sqrt{(41.57 \times 23.38)}$	=	31.18
		3)96.13
The mean area		32.04

$32.04 \times 9 = 288.36$ cubic feet the solid content.

Problem VII.

To find the surface of a sphere, or of any segment or zone of it.

Rule. Multiply the circumference of the sphere by the height of the part required, and the product will be the curve surface, whether it be a segment, a zone, or the whole sphere.

This rule has been investigated in Fluxions (§163.) We shall here give a different investigation.

Let HIKL (Plate CCCLXXII, Fig. 19,) be a square described about a circle, and AB a diameter joining two opposite points of contact. Take D d an indefinitely small arc, and draw DE, de perpendiculars to AB, and produce them to meet the side of the square in F and f. Suppose now the circle and square to revolve about AB as an axis; the circumference will generate a spherical surface, and the side of the square will generate a cylindric surface. Let s denote the spherical zone generated by the arc d D, and c the corresponding cylindric surface generated by the straight line F f; also, put n for 3.1416. Then, since D d, on account of its smallness, may be reckoned a straight line, s may be regarded as the surface of a frustum of a cone. Hence, by Prob. 7. of Part I., and Prob. 5 of this Part.

$s = \frac{1}{2}(n \times 2DE + n \times 2\,d\,e) \times D\,d,$

That is, because DE and $d\,e$ are almost equal,

$s = 2\,n \times DE \times D\,d:$

In like manner, $c = 2\,n \times FE \times F\,f;$

Therefore, $s : c :: DE \times D\,d : FE \times F\,f.$

Draw DG perpendicular to $d\,e$. and DC to the centre, and because of the similar triangles DG d, DEC,

D d : DG : : CD : DE ; or D d : F f : : EF : ED

Hence DE×D d=FE×F f, and therefore $s = c$:

Thus it appears that the corresponding indefinitely small elements of the spheric and cylindric surfaces are always equal, and hence, that any finite portions of them comprehended between planes perpendicular to the axis AB will be equal; so that the truth of the rule is evident.

Ex. 1. What is the superficies of a globe 6 feet in diameter?

First 6×3.1416=18.8496=the circumference.

Then 18.8496×6=113.0976 square feet the superficies.

Ex. 2. What is the convex surface of a segment, 2 feet in height, and cut off from the same globe.

18.8496×2=37.6992 square feet the surface.

Problem VIII.

To find the solid content of a sphere.

Rule I. Multiply the area of a great circle of the sphere by the diameter, and $\frac{2}{3}$ of the product is the solid content.

Rule II. Multiply the cube of the diameter by the decimal .5236, and the product is the content.

The first rule has been demonstrated in Geometry, Part II. Sect. 3. Prop. 6. The second is deduced from the first, thus: put d for the diameter, then .7854 d^2= area of a great circle (Prob. 9. Part I.) and by Rule I. $\frac{2}{3}\,d \times .7854\,d^2 = .5236\,d^3 =$ the solidity.

Ex. What is the content of a sphere 2 feet in diameter?

Answer $2^3 \times .5236 = 4.1888$ cubic feet.

Problem. IX.

To find the solid content of a spherical segment.

Rule. From three times the diameter of the sphere, take twice the height of the segment, then multiply the remainder by the square of the height, and the product by the decimal .5236 for the content.

This rule may be derived from Ex. 3. Art. 161. Fluxions; or it may be found in a more elementary form, (Geometry, Part ii. Sect. 3, Prop. 5.) as follows:

Let CBEF (Plate CCCLXXII. Fig. 20.) be a square described about a quadrant of a circle, and CE the diagonal drawn to the centre. Draw GOHR perpendicular to the radius CF, meeting the diagonal in O, the quadrantal arc in H, and the side of the square in R. Conceive the square to revolve about CF as an axis; then BE, the side of the square, will generate a cylinder, CE, the diagonal, will generate a cone, and the quadrantal arc, BF, will generate a hemisphere, having the common axis CF. Moreover, the line GR will generate a plane, the sections of which, with the cylinder, the hemisphere, and the cone, will be circles, having GR, GH, and GO, for their radii. Now it is sufficiently evident, from the above quoted proposition in geometry, that any section of the cylinder will be equal to the sum of the corresponding sections of the cone and sphere. Hence, if we conceive the three solids to be made up of very thin cylinders having these sections for their bases, it follows that any portion of the cylinder comprehended between two planes, parallel to its base, will be equal to the sum of the corresponding portions of the hemisphere and cone.

Put d for the diameter of the sphere, h for FG the common height of the cylinder EE′R′R, the conic frustum EE′O′O, and the spherical segment HFH′, and n for the number .7854. Then the area of the common base of the cylinder EE′R′R and conic frustum EE′O′O is $n\,d^2$; and because GO=GC, the diameter of the top of the frustum will be $d-2h$, and its area $n(d-2h)^2$; also the mean proportional between the top and bottom will be $n\,d\,(d-2h$. Therefore (by Prob. 3,) the solid content of the frustum is

$$\tfrac{1}{3}\left\{ n\,d^2 + n\,(d-2\,h)^2 + nd\,(d-2\,h) \right\} \times h$$

$$= n\,(d^2 h - 2\,d\,h^2 + \tfrac{4}{3}\,h^3.)$$

Now the solid content of the cylinder is $n\,d^2\,h$ (by Prob. 1.) Therefore the spherical segment, (which is the difference of the cylinder and conic frustum) is

$$n\,(d^2 h - d^2 h + 2dh^2 - \tfrac{4}{3}h^3)$$

$$= \tfrac{2}{3}\,n\,(4\,d - 2\,h)\,h^2$$

This last formula is the analytic expression of the rule.

Ex. In a sphere whose diameter is 21 inches, what is the solid content of a segment whose height is 4.5 inches?

First, 3×21—2×4 5=54.

Then 54×4.5×4.5×.5236=57.25566 inches the content required.

Problem. X.

To find the solid content of a paraboloid, or solid produced by the rotation of a parabola about its axis. (Plate CCCLXXII. Fig. 21.)

Rule. Multiply the area of the base by the height, and take half the product for the content.

This rule has been investigated in *Fluxions*, § 161, Ex. 1.

Ex. If BC, the radius of the base of a paraboloid, be 5, and AB, its height, be 12 feet, what is its content?

First $10^2 \times .7854 = 785.4$ the area of the base;

Next 785.4×6=471.24 feet the solidity.

Problem XI.

To find the solid content of a frustum of a paraboloid.

Rule. Add together the areas of the circular ends; then multiply the sum by the height of the frustum, and take half the product for its solid content.

To prove this rule, put A and a for the ends, h for the height of the frustum, and c for the height wanted to complete the paraboloid. By last problem, the content of the complete solid would be $\frac{1}{2}$ A $(h+c)$ and that of the part cut off $\frac{1}{2}\,ac$, therefore the content of the frustum is

$$\tfrac{1}{2}\,A\,(h+c) - \tfrac{1}{2}\,a\,c = \tfrac{1}{2}\left\{ A\,h + c\,(A-a.) \right\}$$

But from the nature of the parabola A : a : : $h+c$: c and A—a : a : : h : c, hence $c\,(A-a) = a\,h$, and the content of the solid is

$$\tfrac{1}{2}\,(A\,h + a\,h) = \tfrac{1}{2}\,h\,(A+a.)$$

Ex. The diameter of CC′, the greater end of a parabolic frustum, is 58, that of DD′ the less 30, and the height 18 inches. Find the content.

The areas of the ends $= .7854\,(30^2 + 58^2) = 3348.9456$.

The content $= 3348.9456 \times 9 = 30140.5104$ cub. in.

PROBLEM XII.

To find the solid content of a parabolic spindle, or solid generated by the rotation of an arc AEB of a parabola about AB, an ordinate to the axis.

RULE. Multiply the area of the middle section by its length, and take $\frac{8}{15}$ of the product for the content of the solid.

For the investigation of this rule, see Fluxions, Art. 161, Ex. 2.

PROBLEM. XIII.

To find the solid content of a frustum of a parabolic spindle, one of the ends of the frustum passing through the centre of the spindle. (Plate CCCLXII. Fig. 22.)

Add into one sum eight times the square of the diameter of the greater end, and three times the square of the diameter of the lesser end, and four times the product of the diameters; multiply the sum by the length, and this product again by .05236 (viz. $\frac{1}{15}$ of .7854,) and the result will be the content.

Putting $p = $ CD, the abscissa of the generating curve, which is also the radius of the greater end of the frustum, $q = $ AC the semiordinate of the curve, $y = $ CR $=$ PQ the radius of the lesser end of the frustum, $x = $ PR $=$ QC its length, and $n = .7854$; it has been found (FLUXIONS, Art. 161, Ex. 2.) that the content of the frustum is

$$\frac{4\,n\,p^2}{q^4}(q^4\,x - \tfrac{2}{3}\,q^2\,x^3 + \tfrac{1}{5}x^5).$$

Now, from the nature of the curve, $PR^2 : AC^2 :: DR : DC$, that is $x^2 : q^2 :: p - y : p$, hence $q^2 = \frac{p\,x^2}{p-y}$.

Let the values of q^2 and q^4 be substituted in the above formula for the content of the frustum, it then becomes

$$\frac{4\,n\,x}{15}(8\,p^2 + 4\,p\,y + 3\,y^2,)$$

an expression from which the rule is derived.

Ex. Suppose the diameters of the ends to be 8 and 6, and the length 10; required the content.

First $8 \times 8^2 + 3 \times 6^2 + 4 \times 8 \times 6 = 812$,

Then $812 \times 10 \times .05236 = 425.1632$ the content.

PROBLEM XIV.

To find the solid content of a spheroid, or solid generated by the rotation of an ellipse about either axis. (Plate CCCLXXII. Fig. 23.)

RULE. Multiply continually together the fixed axis, the square of the revolving axis, and the number .5236 (or $\frac{1}{6}$ of 3.1416) and the last product will be the solid content.

This rule has been investigated in FLUXIONS, Art. 161.

Ex. 1. The greater axis AB of an oblong spheroid is 50, and the lesser axis CD 30, what is the solid content?

Here the greater is the fixed, and the lesser the revolving axis.

Therefore the solid content is

$50 \times 30^2 \times .5236 = 23562$ the content.

Ex. 2. What is the content of an oblate spheroid, the axes being as in last example?

$30 \times 50^2 \times .5236 = 39270$ the content.

PROBLEM XV.

To find the solid content of the frustum of a spheroid, its ends being perpendicular to the fixed axis, and one of them passing through the centre. (Plate CCCLXXII. Fig. 24.)

RULE. To the area of the less end, add twice that of the greater; multiply the sum by the altitude of the frustum, and $\frac{1}{3}$ of the product will be the content.

NOTE. This rule applies also to the frustum of a sphere.

Investigation.—Let ABE be a quadrant of an ellipse, C its centre, CAFE a rectangle circumscribed about it, and CF the diagonal. Draw any straight line DG parallel to CE, meeting AC, CF, ABE, and EF in D, H, B, G. By CONIC SECTIONS Part 1. Sect. 2. Prop. 16.

$$DB^2 : CE^2 :: CA^2 - CD^2 : CA^2,$$

and by sim. trian $DH^2 : CE^2 :: DC^2 : CA^2$.

Therefore, (GEOM Sect. 3. Prop 10.)

$$DB^2 + DH^2 : CE^2 :: CA^2 : CA^2.$$

Hence $DB^2 + DH^2 = CE^2 = DG^2$.

Suppose now the figure to revolve about AC as an axis, so that the elliptic quadrant may generate the half of a spheroid, the rectangle AE a cylinder, and the triangle ACF a cone; it is evident, as in the case of the sphere, (Prob. 9.) that every section of the first of these solids is equal to the difference of the sections of the other two; and consequently, that the frustum of the spheroid between CE and DG is equal to the difference between the cylinder having DG or CE for the radius of its base, and the cone having DH for the radius of its base, and CE for its altitude.

Put $n = 3.1416$, then (Prob. 4.) the content of the cylinder is $4\,n \times DG^2 \times CD$, and (Prob. 5) the content of the cone is $\frac{4}{3}\,n \times DH^2 \times DC$: Therefore, the difference, or the content of the spheroid, is

$$4\,n \times CD\,(DG^2 - \tfrac{1}{3}DH^2).$$

But it was shewn, that $DH^2 = DG^2 - DB^2$, therefore the content of the solid is equal to

$$\tfrac{4}{3}\,n \times CD(2\,DG^2 + DB^2),$$

and hence is derived the rule.

When the altitude becomes the semiaxis, the frustum becomes half the spheroid, which is $\frac{2}{3}$ of the circumscribing cylinder, agreeing with the rule of Prob. 12.

Ex. Suppose the greater end of the frustum to be 15, the less 9, and the length 10 inches, required the content?

The area of the gr. end $= 15^2 \times .7854$.

The area of the less $= 9^2 \times .7854$

The content $= .7854\,(9^2 + 2 \times 15^2) \times \frac{10}{3} = 1390.158$ cubic inches.

GAUGING.

The geometrical rules by which the content of any cask may be computed, form a particular branch of Mensuration called GAUGING.

Casks are usually considered as having one or other of these four forms:

1. The middle frustum of a spheroid, (computed by Prob. 15.)

2. The middle frustum of a parabolic spindle, (Prob. 13.)
3. The two equal frustums of a paraboloid, (Prob. 11.)
4. The two equal frustums of a cone, (Prob. 6.)

The content of any cask whatever may also be nearly found, in wine or ale gallons, by the following general rule :

RULE. Add into one sum 39 times the square of the bung diameter, 25 times the square of the head diameter, and 26 times the product of the diameters. Multiply the sum by the length, and the product by .00034 ; then the last product, divided by 9, will give the wine gallons, and divided by 11, will give the ale gallons.

In investigating this rule, it is assumed as a hypothesis, that one-third of a cask at each end is nearly a frustum of a cone, and that the middle part may be taken as the middle frustum of a parabolic spindle. This being supposed, let AB and CD (Plate CCCLXXII. Fig. 25.) be the two right lined parts, and BC the parabolic part. Produce AB and DC to meet in E, and draw lines as in the figure. Let L denote the length of the cask, B the bung diameter, and H the head diameter : Then, since AB and DC have the same directions as the parabolic curve BFC, at B and C, they will be tangents to the curve : Therefore $FI = \frac{1}{2} EI$. But $BI = \frac{1}{3} AK$, and hence by similar triangles $EI = \frac{1}{3} EK$; consequently $FI = \frac{1}{2} EI = \frac{1}{6} EK = \frac{1}{3} FK = \frac{1}{10} (B-H)$; so that the common diameter $BL = FG - 2 FI = B - \frac{1}{5}(B-H) = \frac{1}{5}(4B+H)$ which call C. Now, by the rules for parabolic spindles and conic frustums, we obtain (putting n for .7854.)

$$\frac{8 B^2+4BC+3 C^2}{15} \times \frac{Ln}{3} = \frac{328 B^2+44 BH+3H^2}{25\times 45} \times Ln$$

for the parabolic or middle part ; and

$$\frac{C^2+CH+H^2}{3} \times \frac{2Ln}{3} = \frac{160 B^2 + 280 BH+310 H^2}{25\times 45} \times Ln$$

for the two ends, and the sum of these two, after proper reduction, is

$$(39 B^2+26 BH+25 H^2) \times \frac{Ln}{90} \text{ nearly,}$$

for the length in inches ; and the factor $\frac{n}{90}$ or $\frac{.7854}{90}$ being divided by 231 (the inches in a wine gallon) gives $\frac{.00034}{9}$ the multiplier for wine-gallons ; and since 231 is to 252 as 9 to 11 nearly, $\frac{.00034}{11}$ will be the multiplier for ale-gallons, as in the rule.

Ex. Suppose the bung and head diameters of a cask to be 32 and 24 inches, and the length 40 inches, required the content in ale, also in wine-gallons.

Here $(39^2 \times 32^2 + 26 \times 32 \times 24 + 25 \times 24^2) \times 40 \times \cdot 00034 = 1010\cdot 5$, which being divided by 9 and by 11, we obtain 112·3 wine-gallons, or 91·9 ale gallons for the content. (ξ)

MENTZ, or MAYENCE, anciently *Moguntium*, is a city of Germany, in the Grand Duchy of Hesse. It is built nearly in the form of a semi-circle on the left bank of the Rhine, below its junction with the Maine. Mentz is one of the strongest cities in Germany. The works are numerous and strong, and of such an extent as to require a garrison of about 30,000.

The streets of Mentz are narrow and long, and the houses by no means handsome. The principal edifices are the electoral palace, which has been used as a military hospital since 1793, the house of the Teutonic Knights, and the arsenal. The principal churches are, the Cathedral and its towers, the church of Ignatius, the ruins of the church of Notre Dame, the church of the Augustines, the church of St. Peter, and the ancient church of St. Stephen. There is an university at Mentz, founded in 800, and established in 1482 by the Archbishop of Diether, besides some other literary establishments. The public library contains 80,000 volumes, and cabinets of medals, natural history, philosophical instruments, Roman monuments, and pictures.

The trade of Mentz is chiefly in French and Rhenish wines ; and its chief manufactures are those of cotton and coffee of chicory. The population is about 20,000. East Long. 8° 14′, and North Lat. 49° 58′. A very full and interesting account of Mentz, such as it was in 1789, will be found in the *Voyage sur le Rhin depuis Mayence jusqu'a Dusseldorf.* Neuwied, 1791, 2 vols.

MEQUINEZ, or MEQUINAS, the principal city in the province Fez, and the northern capital of the empire of Morocco, is situated in 34° 12′ North Latitude, and about 5° 30′ West Longitude. It stands in a beautiful valley, about 60 miles eastward from Salee, surrounded by gentle eminences and highly cultivated vales. It is an ancient town, founded about the end of the tenth century, by a tribe of the Tenctes called Mequina, who had revolted from the ruler of Fez ; but it owes its present extent and importance to Sultan Muley Ismael. After having subdued the petty kingdoms, which now form the empire of Morocco, he resolved to establish two imperial cities, in order to keep his subjects under more complete authority ; and made Mequinez the capital of the north, as Morocco was of the south. He greatly enlarged the city towards the west, and erected a beautiful palace, with many other public buildings. On the north-west, he enclosed a large space for the families of his black troops, called the Negroes Quarter, and which nearly equalled the city in extent ; but of this black town nothing now remains except the walls. Adjoining to this place is the Millah, or that part of the city inhabited by the Jews, which is walled round and in a good state of repair. On the side of the city towards the Atlas mountains, is a wall of circumvallation about six feet in height, which was built as a defence against the impetuous but momentary attacks of the Berebbers. The palace stands at the south end of the city ; and is a very extensive square, containing several well watered gardens. The buildings are all of one story, and the rooms, though narrow, are long and lofty, being about 12 feet wide, 25 long, and 18 high. The walls are inlaid with glazed tiles of bright colours, and the light is communicated by means of large folding doors. Between the different suites of apartments are courts paved with marble, some of which have a fountain in the centre ; and in different parts of the palace are separate buildings called Kobbahs, which contain a spacious square room with a pyramidal roof, curiously carved and ornamented in the inside. In the centre of the whole is the harem or seraglio, within which is a spacious garden planted with tall cypress trees ; a gallery supported by columns runs round the inside of the square, and communicates with the adjoining apartments, which terminate in a common hall or large chamber, where the females look through the iron-latticed windows, to take the fresh and perfumed air of the gardens. A hospitium, or convent of Spanish monks, was established in Mequinez by the king of Spain, about the beginning of the 18th century, for the relief and spiritual comfort of Catholic captives and Christian travellers; and was much respected by the inhabitants on account of the exemplary lives of the fathers, and the great service which they rendered to the poor by the gratuitous distribution of medicines; but the place was deserted previous to the accession of Soliman, the present emperor.

The houses of Mequinez, like those of other Mahometan towns, have no windows towards the street, except a few small holes, and open into the inner court, which are surrounded with galleries or pillars. The streets are narrow, and without any pavement; so that the mud in winter is accumulated to a degree which renders them almost impassable on foot. The inhabitants are milder in their manners than in any other part of the empire; and are extremely hospitable to strangers. The women of this town are particularly and almost universally distinguished for their beauty; so that the term Mequinasia has become a proverbial epithet for a beautiful woman. Their eyes are large, black, and sparkling, their teeth white, and their complexion of a healthy red and white, forming a striking contrast to the women of Fez, within a day's journey of them, who are generally of a sallow or pale complexion. They have also elegant forms, and possess a modesty and suavity of manners rarely met with in other places, even among the most polished nations of Europe. The population is estimated by Jackson at 110,000. See Chenier's *Present State of the Empire of Morocco;* Jackson's *Account of Morocco.* (*q*)

MERCURY. See Astronomy, and Chemistry.

MERIDA, *the Augusta Emerita* of the Romans, an ancient town of Spain, in the province of Estremadura, is situated on an eminence near the River Guadiana, which is crossed by a large and good bridge. This town, which has now dwindled into insignificance, is principally celebrated for the remains which it still exhibits of Roman magnificence. The pavements of the streets, of the houses, and the churches, are so many vestiges of their works, and the wells and the cellars are filled with them. Numerous inscriptions, ruined columns, vases, capitals, friezes, statues, and basreliefs are everywhere seen. Two Roman aqueducts are still seen in ruins, and also the vestiges of a fortress. The ancient baths are in an excellent state of preservation. Besides these, there are two large reservoirs of water like lakes, called Albufera and Albuera, which appear to have been used for combats on the water. One of them, which is a league from Merida, is 90 feet long, and 51 deep. It is surrounded with thick walls, and adorned with two beautiful towers, a very fine flight of steps leading to the bottom. The other reservoir, which is 2 leagues from the town, is small, but the walls which retain the water, and the great tower which serves it for an aperture for air, are much finer. The environs of Merida abound in corn, wine, and fruits. Its population is about 4500. West Long. 6° 3′, and North Lat. 38° 48′. See Laborde's *View of Spain*, Vol. i. p. 347.

MERIDE, a *musical interval*, was so named by M. Sauveur, (see *Mem. de l'Acad.* 16mo, 1701, p. 407) as the $\frac{1}{43}$ part of the octave, $= 14.2761314\Sigma + m, = 14.2839938\,\Sigma$; its common log. is .9929993,0243; and it is equal to 7 Eptamerides, which see.

MERIDIONAL PARTS. See Navigation.

MERIONETHSHIRE, a maritime county in North Wales, is bounded on the north by Caernarvonshire and Denbighshire; it is divided in part from the former county by an immense ravine, through which flows a small river; on the east by Denbighshire and Montgomeryshire; the division of it from the latter county is partly formed by one of the most celebrated passes in Wales, called the Stoney Mile; on the west it is bounded by the Irish Sea; and on the south by Cardiganshire, from which it is divided by the river Dovey. Its form is nearly that of a triangle, the apex of which is to the south. Its length, from the vicinity of Snowdon to the confines of Montgomeryshire, is 43 miles, and from Harlech to the boundary of Llangollen parish, it is about 38 miles broad. Its circumference is about 154 miles, and its area 691 square miles, or 442,240 acres. It is divided into 5 hundreds, and contains one county town, Harlech; the other towns are Dolgelly, Bala, and Burmouth. The surface of the county, though on the whole very mountainous, is a good deal varied, as there are some lower hills, and beautiful and fertile valleys, interspersed with woods, lakes, rivers and cataracts. These circumstances, together with the grandeur of its sea views, render it one of the most romantic and picturesque of the Welsh counties. Some of the principal mountains and vales deserve a short notice. At the north-eastern angle of the county is a long chain of mountains which branches into Denbighshire and Montgomeryshire; they are called the Ferergn Mountains; their northern boundery is the Dee, and their southern the Tannad; their length from north to south is about 16 miles, and their breadth varies from 5 to 10. There are no lakes in these mountains, and no river of consequence flows from them. The fine vale of the Dee lies below them. The other most celebrated mountains are Cader Idris and the two Arrans. Cader Idris is the beginning of a chain of mountains which, beginning near the sea, about a mile above Towyn, extends in a north and north-easterly direction, and includes the Arrans. It is in height the second in all Wales. Its peak rises above the town of Dolgelly about 2,850 feet. It is very steep and craggy on every side, and nearly perpendicular on its southern, on the borders of Talyllyn lake. The breadth of this chain in no part exceeds 4½ miles, and in some parts it is a mere ridge. The loftiest of the Arrans is said to be only 120 feet below Cader Idris. Beyond this mountain, towards the sea, are round smooth hills, which form a rich and excellent sheep walk, and then meadows and bogs. To the north of Dolgelly there is a mountainous tract, containing several lakes; this tract extends to the north part of the county, which is celebrated for the beautiful vale of Festiniog This vale is scarcely 3 miles long, and not one in breadth. There are few vales which afford such delightful prospects; the hills which bound it are covered with oaks, and a small and beautiful river flows in a serpentine course through it, in the midst of rich cultivated fields. Near the vale are the falls of the Cynfaol: the upper consists of three steep rocks, over which the water falls into a black bason, which is overshadowed by other rocks; the other is formed by a broad sheet of water precipitated about forty feet. The principal lake in this county, and indeed the largest lake in all Wales, is Pemblemoer or Bala Pool, on the banks of which stands the town of Bala; from north-east to south-west it is 4 miles long; its greatest breadth is 1,200 yards. Its water is said to be so pure that the most delicate taste cannot detect any admixture. The scenery around it is mountainous, but not grand or picturesque. In stormy weather its waters are raised 8 or 9 feet, covering the adjoining vale, and sometimes threatening destruction to the town of Bala. The river Dee flows through this lake. There are several other lakes of smaller size, some of which are remarkable for the beauty of the surrounding scenery.

The principal rivers are the Dee, the Descenny, the Dyssi, the Avon, and the Dyrwhydd. The Dee has two spring heads, in the eastern part of the county, near the sides of the Arran mountain; these, after uniting and passing through the lake of Pemblemoer, run by a north-east direction into Denbighshire. The Descenny rises about 3 miles to the south of Dolgelly, and falls into the Irish sea a little to the west of Towyn; the Dyssi or Dovy rises in the west part of the county, and falls into the Irish Sea at Aberdovy. The Avon rises to the south-west of Bala, passes by Dolgelly, and falls into the Irish sea a little below Barmouth. The Dyrwhydd rises in the north of the county, on the borders of Caernarvonshire, and falls into the Irish sea about 3 miles north from Harlech. The coast of this county possesses only one port, Barmouth, which stands on a little arm of the sea, and is of difficult entrance, the bar admitting only vessels that draw 8 or 9 feet, even at high water. On the northern part of the coast adjoining Caernarvonshire, are two inlets of the sea, Troeth Bach and Troeth Maivr, having one entrance, and each receiving a small stream; the greatest part of them are dry at low water, and become quicksand. 2000 acres of the latter have lately been recovered by embanking. Tradition states, that a whole division or hundred of this county has been swallowed up by the sea, and there are appearances that strengthen it. This hundred is said to have stretched north and south 12 miles, and to have been about 5 in breadth; and to have been situated between Harlech and Barmouth. About half way between these towns is a causeway, 24 feet thick, which runs for a considerable way into the sea, the end of which is met by another causeway, which stretches out from a point to the north-west of Harlech. The space between these is supposed to have been the hundred. The inundation is said to have happened about the year A. D. 500. The natural history of this county, so far as its mineralogy is concerned, is rather interesting. The mountains consist principally of granite, porhpyry, and other unstratified rocks. The secondary hills are composed of mixed schistus; the vallies contain schistose clay, and the level parts of the county abound with peat earth. The Ferwyn mountains are composed of primitive schistus, in thick irregular laminæ, intersected in places with veins of quartz. There are large quarries of slates in those mountains. The only metals found in them are calamine and lead. Cader Idris consists of siliceous porphyry in mass, intersected by vines of quartz. Siliceous schistose porphyry also intersected by viens of quartz; argillaceous prophyry in mass, and granitell in mass. There are no mines in or near Cader Idris. The lake of Bala abounds in a variety of fish, of which the red trout and the gwyniad are the rarest and most esteemed. It is remarked that the trout in the Dee have white flesh, whereas those in the lake have theirs always red. The climate of this county is very cold, and at the same time moist, and is said to be particularly unfavourable to fruit. The soil in some part of the vallies is fruitful, but in general it is very sterile.

After having described the surface, the mountains and lakes of Merionethshire, little remains to be said of this county, for its agriculture cannot be a matter of any importance, when we reflect on the nature of its soil, surface, and climate, all of which are unfriendly to agriculture. In its valleys, potatoes, barley, and oats are cultivated on a small scale, and in an inferior manner; the pastures in these valleys are good, and the less lofty hills, especially on the sea-coast, near the mouth of the Dovey, furnish extensive and excellent sheep-walks. In other parts of the county, breeding and the dairy are attended to with some spirit and success. Though it is even at present well wooded, especially when compared with the adjoining county of Caernarvonshire, yet, formerly, from the account of Leland, it appears to have been much more thickly covered with timber. There are one or two large trees in it, which deserve notice. In the church yard of Malwydd is a remarkable yew tree: the girth of the trunk, a yard high, is 22 feet and a half, the radius of the branches 39 feet, forming a circumference of about 240 feet. The peasantry near Harlech, chaunt with the harp some verses in celebration of an oak tree, the trunk of which, 15 feet in length, and 25 in circumference, measured 609 cubic feet. From the fork it divided into several branches, 3 of which extended to the length of 45 feet. The roads of this county have been much improved within these few years. From the accounts laid before Parliament, it appears that in the year 1814, the length of the paved streets and turnpikes in this county was 206 miles 2 furlongs; and the length of all the other highways 393 miles 1 furlong. The estimated value of labour expended on their repairs, was 775*l.*; the composition money, 449*l.*; the highway rates, 180*l.*; and the money expended in law, 8*l.*; making a total of 1102*l.* for the maintenance of 599 miles three furlongs of streets and highways.

Merionethshire is celebrated for its woollen manufactures; strong cloth is made principally near Dolgelly. Almost every little farmer makes webs; and few cottages are without a loom. The cloth is generally sold on the spot, though some is still sent to Shrewsbury; a great deal is exported through Liverpool and London to Holland, Germany, and America; the rest is used at home. Stockings, wigs, socks, and gloves, are made in the town and neighbourhood of Bala; they are generally purchased by chapmen, who sell them in the adjoining English counties.

This county returns one member to Parliament; is partly in the diocese of Bangor, and partly in that of St. Asaph, and in the province of Canterbury. The following are the results of the returns to Parliament respecting its poor, for the year ending the 5th of April, 1815.

Annual value of real property	£111,436
Money raised by parochial rates	14,254
Money expended for the poor	12,096
Money in removals, suits of law, &c.	425
Money for militia purposes	50
Church rate, county rate, &c.	1713
Total expenditure	£14,285

Persons relieved out of workhouses	2213
Persons relieved in ditto	none
Occasionally in and out of ditto	386
Members of Friendly Societies	34
Annual amount of charitable donations for parish schools	£84 0
——— for other purposes	221 18

In the year 1803, the parochial rates amounted to the sum of 9,449, so that in 1815 there had been an increase of nearly 50 per cent.

The following are the results of the last population return: in the year 1700, 23,800 inhabitants; in 1750, 30,900; in 1801, 30,500, a decrease; and in 1811, 30,924; from this it appears that the population in 1811, though greater than that in 1801, scarcely exceeded that in 1750. There is one baptism to 40 inhabitants; one burial to 62, and one marriage to 129.

Houses inhabited	6220
Families occupying them	6817
Houses building	33
Houses uninhabited	115
Families employed in agriculture	3619
Families in trade	1270
All others	1928
Males	14,308
Females	16,616
Total	30,924

See Davies's *View of the Agriculture of North Wales*; Aikin's *Tour through North Wales*; and Nicholson's *Cambrian Traveller's Guide*. (W S.)

MERMAID, or MERMAN, a marine animal, the upper parts of which are supposed to resemble those of the human species, and the lower the tail of a fish.

This animal, such as it is understood to be, has never come under the observation of any intelligent naturalist, and has therefore given birth to many controversies. Artedi, however, proposes to institute a genus under which the mermaid may be comprehended with these characteristics, SIREN, Dentes . . . . . . Pinnæ *duæ tantum in toto corpore. Canda pinnata nulla.* Caput, *collum et pectus ad umbilicum usque, humanam speciem habent.* But, at the same time, he says, "I wish that some skilful ichthyologist would examine this animal, to ascertain whether it be imaginary, or a real fish; it is better to refrain from opinions, than to give them precipitately." *Bibliotheca Ichthyologica.* Others have shown less reserve, and have declared positively that the mermaid is an animal *sui generis*, narrowly resembling the human species.

The ancients describe Sirens, Tritons, and Nereids, as inhabitants of the waters; and it has been generally believed by the natives of all maritime countries, that such beings actually exist; but the discrepancies in the description by those who have seen the mermaid, or merman of modern times, are such that they cannot refer to the same animal. Some affirm it is smooth; others call it hairy; and, according to a third class, it is covered with scales. There is the like difference regarding the real figure of the animal, which is said either to have a single or divided tail; or to have none; as seems to be the case with that alluded to by Artedi.

In an early account of Newfoundland, the narrator describes a "maremaid, or mareman," which he observed within the length of a pike, as a strange creature, which came swimming swiftly towards him, "looking cheerfully on my face, as it had been a woman. By the face, eyes, nose, mouth, chin, ears, neck, and forehead, it seemed to be so beautiful, and in those parts so well proportioned, having round about the head many blue streaks resembling hair, but certainly it was no hair." The observer further remarked, that the shoulders and back, down to the middle, were square, white, and smooth, as the back of a man: and from the middle to the end, it tapered like a broad-hooked arrow. This animal put both its hands on the side of the boat wherein he sat, and strove much to get in, but was repelled by a blow. (See Whitbourne's *Discourse of Newfoundland* in fine.) Probably the narrator's imagination has embellished the appearance and the boldness of the animal. In the year 1671, another marine animal was seen by six negroes, who, being strictly examined on the subject, agreed, in general, that from the head to the middle it resembled a man, and from thence downwards a fish, terminating in a forked tail; the head, face, eyes, and mouth, were like those of a man; the nose extremely flat. Its hair, which was grey, hung over the shoulders; and the beard, also grey, was about seven or eight inches long. Grey hair covered the breast, but the throat and rest of the body were rather white. The size of the animal was about equal to that of a youth of 16 or 17. It stood half out of the water, looking boldly on the negroes, and raising its hand as if to wipe its face: it was within a few paces of them; and, after showing itself three times, plunged into the sea. De Maillet, *Telliamed*, tom. ii. p. 320.

Nearly about the same period, there was given a very distinct account of an animal referred to this tribe, though the author, an English surgeon, does not design it by any name. About three leagues from the mouth of the river Rappahannock in America, while alone in a vessel, he observed, at the distance of about half a stone throw, "a most prodigious creature, much resembling a man, only somewhat larger, standing right up in the water, with his head, neck, shoulders, breast, and waist, to the cubits of his arms, above water; his skin was tawny, much like that of an Indian; the figure of his head was pyramidal and sleek, without hair; his eyes large and black, and so were his eye-brows; his mouth very wide, with a broad black streak on the upper lip, which turned upwards at each end like mustachios. His countenance was grim and terrible. His neck, shoulders, arms, breast, and waist, were like unto the neck, arms, shoulders, breast, and waist of a man. His hands, if he had any, were under water. He seemed to stand with his eyes fixed on me for some time, and afterwards dived down; and a little after rose at somewhat a greater distance, and turned his head towards me again, and then immediately fell a little under water, that I could discern him throw out his arms, and gather them in as a man does when he swims. At last he shot with his head downwards, by which means he cast his tail above the water, which exactly resembled the tail of a fish with a broad fane at the end of it." Glover's *Account of Virginia, Ap. Phil. Trans.* vol. xi. p. 625, for 1676.

The mermaid is not confined to any quarter of the globe; for according to Debes, in 1670 one stood near the shore of the Faroe Islands, in sight of many of the inhabitants, during two hours and a half, up to the navel in the water. "Long hair hung from her head all around her, down to the surface; and she held a fish in her right hand." The modern historian of these islands, Landt, is silent on this subject.

Pontoppidan, a credulous author indeed, yet willing to take a comprehensive view of doubtful subjects, affirms, that if the existence of European mermaids be called in question, it proceeds entirely "from the fabulous stories being generally mixed with the truth." Hundreds of persons, of credit and reputation in the diocese of Bergen, maintained, with the strongest assurances, that they had seen this creature, sometimes at a distance, sometimes quite close to their boats, standing upright. It was formed like a human being down to the middle, but they could not see the rest. Nevertheless, Pontoppidan could find only a single person who had actually seen and handled one out of the water. His informer, a clergyman, said, that in the year 1719, a merman had been cast up dead on the shore, along with other fish. It was much longer than any others described. "The face resembled that of a man, with mouth, forehead, eyes. The nose was flat, and, as it were, pressed down to the face, in which the nostrils have ever been very visible. The breast was not far from the head; the arms seemed to hang to the side, to which they were joined by a thin skin, or membrane. The hands were, in appearance, like to the paws of a sea-calf." *Natural History of Norway*, vol. ii. p. 190, 191. Pontoppidan observes, that the most recent account of the animal related to the year 1723, when three ferrymen affirmed on oath, that one had been seen by them at the distance of not more than 7 or 8 fathoms. In appearance, it resembled an old man with strong limbs and broad shoulders: its skin was coarse, and very hairy. The head was small in proportion to the body, and had short curled black hair, which did not reach below the ears. The face was meagre, the eyes deep sunk, and the beard black. It stood in the same place half a quarter of an hour, exposed down to the breast, and the tail was remarked to taper like that of a fish. The men, beginning to be alarmed, retreated, when the animal, inflating its cheeks, made a kind of roaring noise, and plunged into the water. One of the same ferrymen affirmed, that 20 years before, he had seen a mermaid with long hair and large breasts. Pontoppidan adds, that a creature is often caught on the hooks of fishermen, which he inclines to call the offspring of the merman, some being as large as a child of three years old. One had been taken recently, which, in the upper parts, resembled a child, but the rest of it was like a fish. Vol. ii. p. 195.

Torfæus maintains, that mermaids are seen near the southern coast of Iceland; and according to Olafsen, two have been taken in the surrounding seas; the first in the earlier periods of the history of that island, and the second in 1733. The latter was found in the belly of a shark. Its lower parts were consumed, but the upper were entire. This creature was as large as a boy eight or nine years old; the head shaped like that of a man, with a very prominent occiput; and the forehead broad and round. The ears were situated far back, and had large lobes. On the head was long stiff black hair, hanging down to the shoulders, pretty much resembling the *fucus filiformis*. The skin above the eyelids was greatly wrinkled and bald; and throughout the body, of a clear olive colour. The eyes resembled those of a cod; and both the cutting teeth and grinders were long, and shaped like pins. The arms were of the natural proportion, and each of the five fingers connected by a large web. The neck was short, the shoulders high, and the breast and back exactly resembling those of a man. Olafsen considers the pecularities of this animal to be demonstrated in the hair, teeth, and fingers. But, from the rapid change taking place in the stomach of a shark, and the great distance it can speedily traverse, he is almost inclined to believe that these were human remains. Yet the islanders were differently impressed; for all firmly credited this creature to be the *marmenill*, by which name the mermaid is known among them. Olafsen *Voyage en Islande*, tom. iii. p. 223.

The attention of the public has been more lately attracted to accounts of mermaids, supposed to have been seen on the coast of Scotland and Iceland. According to old historians, some remarkable animals were taken on the coast of England, which were called "a triton, or man fish;" but no accurate and authentic description has been transmitted, from which we are enabled to determine regarding their nature. In the course of last century, also, a plate was engraved, we have understood, of a marine animal, by the same denomination, which was taken about the year 1746 or 1747. It is generally credited, among the inhabitants of the northern coast of Scotland, that the mermaid inhabits the neighbouring seas; and Mr. Munro, schoolmaster of Thurso, affirms, that about the year 1797 he observed a figure, like a naked female, sitting on a rock projecting into the sea, at Sandside Head, in the parish of Reay. Its head was covered with long thick light brown hair, flowing down on the shoulders. The forehead was round, the face plump, and the cheeks ruddy; the mouth and lips resembled those of a human being; and the eyes were blue. The arms, fingers, breasts, and abdomen, were as large as those of a full-grown female. This creature was apparently in the act of combing its hair with its fingers, which seemed to afford it pleasure; and it remained thus occupied during some minutes, when it dropped into the sea. The observer did not remark whether the fingers were webbed. On the whole, he infers that this was a marine animal, of which he had a distinct and satisfactory view, and that the portion seen by him bore a narrow resemblance to the human form. But for the dangerous situation it had chosen, and its appearance among the waves, he would have supposed it a woman.—Twelve years later, and not very distant from the same spot, as we conjecture, several persons observed what was supposed a mermaid. It floated at the distance of only a few yards from them, and remained in sight about an hour. Nothing except the face was at first visible; and as the sea run high, the creature sunk gently under the waves, and then re-appeared. The head was very round; the hair thick and long, of a green oil cast; and it appeared troublesome when thrown over the creature's face by the waves. As they receded, it removed its hair with both its hands, which, as well as the arms and fingers, were very long and slender. The last were not webbed. The forehead, nose, and chin, were white, and the whole side face of a bright pink colour; the throat was also white, slender, and smooth; and the smoothness of the skin, on which neither hair nor scales were observed, particularly attracted attention. The face seemed plump and round; the eyes, of a light grey colour, were small, as also the nose. The mouth was large; and, from the jaw bone, which was straight, the face was apparently short. One of the arms was frequently extended over the head of the animal, as if to frighten a bird, which, hovering about it, seemed to distress it much. When this had no effect, the creature turned round several times successively. Both here, and in the former instance, the sun shone bright, and the objects were sufficiently near the observers.

Nearly three years afterwards, in October 1811, a singular creature is said to have been seen on another part of the coast of Scotland, remote from the former. A peasant made oath in presence of a magistrate, that about four miles south of Campbeltown, his attention was attracted by a white object on a black rock. He crept through a field of corn, and then advanced among the rocks on the shore, until he approached within 12 or 15 paces of it. The upper part was white, and resembled the human form, and tapered gradually towards the tail, which terminated like a fan 12 or 14 inches broad. The under half was of a brindled or reddish grey, apparently covered with scales; but the extremity of the tail itself was of a greenish-red shining colour. Its whole length appeared to be four or five feet, and it was of the thickness of a youth. The head, hair, arms, and body down to the middle, resembled those of a human being; but as the creature lay flat on the rock, and with its head towards the sea, and was constantly stroking and washing its breast, the peasant could not discover whether or not the bosom was formed like that of a woman. The neck and arms seemed short in proportion to the body. Long light brown hair covered the head, which being sometimes raised over it by gusts of wind, the animal leaned towards one side, and with her hand on the other stroked it back, then shifting its position, adjusted it in the same manner on the opposite side. During two hours it remained thus exposed to observation; but the tide having receded, so as to leave the rock dry five feet above the surface of the water, the animal, leaning forward on one arm, then on the other, drew its body towards the edge, and tumbled clumsily into the sea. Now for the first time the face was distinctly seen, having all the appearance of the human aspect, with very hollow eyes, and the cheeks of the same colour as the rest of the face.

Still more lately it has been affirmed, that in the course of autumn, 1819, a creature appeared on the coast of Ireland, about the size of a girl of ten years of age, with a bosom as prominent as that of one of sixteen, having a profusion of long dark brown hair, and full dark eyes. The hands and arms were formed like those of man, with a slight web connecting the upper part of the fingers, which were frequently employed in throwing back and dividing the hair; and the tail appeared like that of a dolphin. This creature remained basking on the rocks during an hour, in the sight of numbers of people, until frightened by the flash of a musket, when it plunged with a scream into the sea.

These are some of the most recent narratives regarding marine animals, that had a resemblance to the human figure. But a question naturally arises, what were these animals? Had they actually some of the parts and proportions of man, or do they belong to another order, on which credulity and inaccurate observation have bestowed a false character?

We are, no doubt, very imperfectly acquainted with a multitude of animals, especially those of the aquatic tribes; and the learned Bishop of Bergen justly exclaims, "Were it possible that the sea could be drained of its waters, what incredible numbers, what infinite variety of uncommon and amazing sea monsters would exhibit themselves to our view, which are now entirely unknown." *Natural History of Norway*, vol. ii. p. 185. Many, however, have supposed, that because a narrow link appears between the human and the brute creation on land, the same should exist in the sea; and various other causes have contributed to the prevalence of this opinion. Nevertheless, the most skilful naturalists of the present age deny the existence of the mermaid: regarding those seen in the sea, as some of the various species of seals; and those exhibited as such on shore, as natural subjects disguised by art. The triton of Ælian and Pliny are different; the *woman fish* of Santos, Barchewitz, Bartholin, and Artedi, cannot be considered the same; nor can any of those animals we have described be referred to the *Musague* of the Pelew islands, sixteen feet long, and twelve in circumference, which has been lately classed with "the merman of Norway." The nature and properties of the seal are yet susceptible of many illustrations; and some have found an imperfect resemblance of the human form in certain organs, to the corresponding parts of phocæ. Parsons, *ap. Phil. Trans.* vol. xlii. p. 383. A recent voyager to the North remarks, that "these animals, in swimming, often raise themselves as far as the shoulder above the surface of the water. The first I saw in this position was at a considerable distance, and might easily have been mistaken for a man." Laing, p. 107. But the illusion may be heightened still farther; for, according to some authors, the *woman fish* of the African seas, when taken in nets by the Negroes, shrieks and cries like a woman. Captain Colnett relates also, that in the South Seas, when far from land, an animal arose beside the ship, and uttered shrieks and lamentations, so like those proceeding from a woman, as to occasion great alarm. They continued for above three hours, and seemed to increase as the ship withdrew. Captain Colnett conjectured that they came from a female seal that had lost its cub, or a cub that had lost its dam, but he declares that no resemblance could be nearer the human voice. *Voyage to the South Seas*, p. 169. The extreme rarity of what has been called the mermaid, is far from being an argument against its existence. During late years, naturalists scarcely believed in the giraffe and hippopotamus; they still debate concerning the unicorn and the mammoth; and that such a creature lived as the great sea serpent, was resolutely denied, until one was cast up by the waves on our own islands. The existence of a marine animal, partly resembling the human species, is therefore to be considered a question of evidence, which remains to be decided. (*c*)

MERSEY. See England.

MERTHYR Tydvyl, is an ill-built and irregular town of Wales, in the county of Glamorgan. It is situated on the river Tay, in the midst of bleak hills, and derives its importance from the iron forges in its neighbourhood. There is here a parish church, which is a large and handsome building, about eleven meeting-houses, a philosophical society, a printing-house, and a theatre. The iron works are on a very large scale, and strangers are much interested by the celebrated water wheel, 100 feet in diameter. No less than 250 tons of iron ore are said to be furnished weekly, and 240 tons of coal consumed daily. The articles which are here manufactured are exported by means of navigable canals to Cardiff, in vessels of 300 tons. Number of houses 240. Population 1256.

MESSINA, a city of Sicily, situated at the north-east extremity of that island, and on the eastern shore of the Straits of the same name, which are particularly celebrated from containing Scylla and Charybdis within their precincts. They are formed by a promontory of Calabria on the continental side, and Cape Pelorus on the Sicilian coast, the intermediate distance being about two miles. Scylla is a lofty rock, rising abruptly from the sea, on the shore of Calabria, 12 miles north-west of Messina: it is surmounted by a castle, and declines towards the town of Scylla on the coast. At the distance of two miles from it a murmuring noise like the confused barking of dogs is heard, which is occasioned by the dashing of the billows among the caverns below: and hence the ancients fabled a hideous female monster, surrounded by ferocious animals, ready to devour those mariners who came within her reach. In calm weather no danger is to be apprehended, but a vessel brought into the conflicting wind and the current of the Straits, which sometimes runs with great violence, is still exposed to destruction.—Charybdis, described as a raging whirlpool, which absorbed whole vessels with their crews, and then rejected the broken fragments and mangled bodies, lies 750 feet from the city. At present, when viewed from the shore, it appears like a body of water in tumultuous agitation, and on nearer approach the waves are discovered to be larger and more disturbed, dashing together, so as to produce a revolving motion among themselves, throughout a circle of about 100 feet in diameter, where the sea is 500 feet deep. The smallest barks may now cross it in safety; but when a strong wind and current are opposite, the waves become more turbulent and extensive, and three or four, or a greater number of whirlpools, are formed: Vessels driven among them are not manageable, and if unassisted by the pilots of the country, they founder, or are impelled on the opposite shore, and wrecked. Charybdis, however, is not properly a vortex; it has no power of absorption; and vessels, on the contrary, are rather repelled from it by a centrifugal force. Though extricated from Charybdis, a ship meeting an adverse wind, on leaving the Straits, may fall on Scylla, thus verifying the words of the ancients. Twenty-four pilots are kept in the service of the Sicilian government, to assist vessels navigating these Straits, which were passed for the first time by a modern fleet, it is said, when the British advanced to the battle of the Nile.

One side of the city of Messina rises from a narrow plain on the shore, along the declivity of a chain of mountains, finely wooded and diversified, and another sweeps along the margin of a beautiful harbour. It is built with considerable regularity, nearly in the figure of a parallelogram, and consists of two long principal streets, besides a third on the quay, intersected by a number of others, at right angles, all of which are paved with large blocks of lava from the volcanoes of the island. It contains several squares and open spaces, embellished with a number of statues and fountains, the latter copiously supplied from the neighbouring mountains; from whence also torrents descend through the streets, where they are confined by walls to prevent their injuring the buildings. A street called the Marina, or Palazzata, formed of a row of lofty elegant buildings, extends above a mile along the harbour, where the great depth of water admits of the largest vessels approaching to the very edge. It is penetrated by eighteen or nineteen gateways, leading to the respective streets in the city, over which are sculptured appropriate designs and inscriptions; and one end terminates with the royal palace. A considerable portion of the whole, however, as well as the statues in front of these edifices, was ruined in the year 1783, and is scarcely yet completely restored.

Messina contains numerous public edifices, among which are about fifty churches, many of fine architecture, and internally decorated with paintings, for the most part from the pencil of native masters. The cathedral, a spacious building of Gothic architecture, and highly embellished within, stands in an irregular square, where there is a bronze equestrian statue of Charles III. of Spain in the centre. Antique granite columns, brought from a temple of Neptune once standing on the Straits, support the vaulted roof and the timber work of the nave. The great altar consists of mosaic, richly executed in jasper, agate, lapis lazuli, remarkable marbles and pastes of various colours, whose combination, together with gilded bronze, produces an imposing effect. There is a marble pulpit here, the work of Gaggini, a Sicilian sculptor of the sixteenth century, which is much admired. This cathedral was erected by Roger, Count of Sicily, in the end of the eleventh, or beginning of the twelfth century; it is dedicated to the Virgin Mary, an original letter from whom, addressed from Jerusalem to their progenitors, the Messinese boast of yet possessing. Messina is an archiepiscopal see. Directly opposite to the cathedral there is a fountain, ornamented with a number of fine marble statues of nymphs and deities, alike elegant in design and execution. It is to be remarked, that some parts of the city, such as the *Square of the Four Fountains*, are named from the structures of this kind embellishing them.

Here there are not fewer than thirty convents for both sexes, which for the most part are very large, and highly ornamented with all the symbols of the Catholic faith.

The public hospital is a fine building, capable of receiving several hundred patients. It is supported by considerable revenues, arising from lands and houses, and is managed by a committee of noblemen. But, owing to prevalent abuses, there are few patients admitted, and even these are not suitably treated, both from the want of necessary attendance, and from too rigid economy. The other charitable institutions, consisting of six asylums for the poor, a house for the reception of foundlings, and two *montes di pieta*, labour under similar defects. These last are public offices under government, where money at a small per centage is advanced on goods to the necessitous, and the profits applied to support seminaries for the education of youth. Such institutions subsist in various towns of Sicily, where they are productive of the most beneficial effects, and obviate the inconvenience which is felt in other countries from the loan of money by individuals on pledges. The public prison, which by a singular deviation from a real sense of its purpose, is exhibited in a very fine structure, in one of the principal streets; it is spacious within, and superior to that of the capital in certain respects, but deficient in most of the essential requisites of such a place; cleanliness, for example, and in the sexes being separated, which are precautions alike important to health and morals. Messina also contains two houses of correction for women. The royal palace and senate-house are fine buildings.

There are four public libraries, but only two of them are of importance. The British residents in Messina, however, have established reading rooms. A newspaper, said to be the only one in the island, is published here, in Italian, called the *British Gazette*.

The state of the drama is considered very low in Messina, and the theatre in every respect unworthy of so large a population. Friday is selected for the performance of tragedy, on which evening the theatre was shut previous to the dissemination of the writings of Alfieri. From the scarcity of public amusements, gaming tables are frequently resorted to, especially by the more fashionable Sicilians.

The city is defended by two forts, Gonzago and Matagrifone; and the harbour is protected by a pentagonal fortification, called the citadel, which was erected in the year 1679. This is the strongest place in the island, and it has casemates for 5000 men. Near to it is a lazaretto, which, notwithstanding the prevalence of the plague in many parts of the Mediterranean, is the only one in Sicily; and so little regard is paid to safety, that the restrictions both on landing goods and the crews of ships under quarantine are very easily evaded.

The harbour of Messina is the best port of Sicily, containing not less than from 20 to 40 fathoms water, close to the quay, and its situation is esteemed superior to any other in the Mediterranean. Hence this city has been always a place of considerable trade. A large proportion of the produce of the island, affording no less than ninety-six articles of export, is to be found in the city. The produce of the environs is principally fruits and wines, and the chief manufacture consists of silks. What is called the Faro red wine, is in great repute with the British on account of its strength and resemblance to port, which it also equals in quality when kept three or four years. In addition to the quantity made for home consumption, about ten thousand pipes are exported yearly. The other exports are dried figs, citrons, oranges, lemons, lemon juice, manna, essence of bergamot, red tartar, goat skins, hides, mottled soap, for the American market, linen and rags, partly to England, partly to the Italian ports. Some time ago it was computed that there were exported 2000 chests of oranges, and 6000 chests of lemons, each containing 408; likewise 280 barrels of lemon juice. During several centuries silk-worms have been successfully reared in the vicinity of Messina, and their produce is to be ranked among the first sources of its opulence. There are several extensive manufactories of that article here, and many years since 1200 looms were employed in the city. The silks, however, are not highly esteemed, but by the recent introduction of the machinery constructed in Britain, their fabric throughout Sicily is in a state of progressive improvement. An ample assortment of the produce of the Levant and the Morea is brought hither by the Greeks, consisting of carpets, silks, cotton, timber, fruits, gums, drugs, and other merchandize. During later years a number of British merchants have settled here, by whom an active commerce is prosecuted, yet it is supposed with less real advantage than their original prospects contemplated. Messina is a free port, but not in the full acceptation of that term: and the inhabitants, in consequence of the misfortunes of the city, have had an immunity from taxes for 25 years.

Part of the inhabitants find occupation in the coral fishery; and in that of the sword-fish and shark during certain seasons of the year. About eighteen or twenty vessels are engaged in the first, each navigated by eight men, who are exclusively Messinese, on account of their superior personal strength and skill, and also from the dangers attending it. They obtain nearly 3000 pounds of coral yearly; but the fishermen consider this a secondary employment, and to be followed only when none more profitable occurs. In the capture of the sword-fish, from eight to twelve barks, each provided with two boats, are employed. The fishermen use either strong nets or a harpoon, which is so constructed, that, on striking the fish, the shaft is disengaged from the iron head, while both are retained by a cord 600 feet long. Much dexterity is practised here; and the fishermen, who are very superstitious, repeat a Greek sentence, as a charm to attract the fish to their barks. Most of those taken are consumed in Messina, where this fish is favourite food; and some, being salted, is sent in presents to Naples. The fishery of the shark is not regularly followed, as it resorts, at uncertain periods, to the Straits; and the occupation is attended with danger, from the great voracity of the creature.

The judicial establishments exceed all proportion to the population, which in itself produces many inconveniences; and the inhabitants are greatly dissatisfied with the discharge of the duty of their functionaries. There is a senate, consisting of fifteen members, or officers, civil and criminal courts, whose proceedings are subject to appeal in the courts at Palermo, and civil officers superintending the whole, amounting to no less than 300. It is impossible to obtain a prompt decision, which keeps a number of litigants constantly at law; and, in consequence, a great many professional persons find employment. Justice is very partially administered, which is the source of great annoyance to the parties; and the police of the city is bad. A few years ago, an Englishman having been robbed and murdered in the streets, his mercantile countrymen resident here demanded the punishment of the offenders, who, after much equivocation and delay, were convicted. Nevertheless, their relatives endeavoured to redeem them from the penalty by bribery; and it required the most vigorous efforts to obtain their execution. Forty-eight villages are dependent on the city, and governed by the same laws.

Messina is the second city in Sicily, and is at present in a high state of prosperity, notwithstanding the defects of its internal administration. The population of few cities has undergone greater fluctuation within an equal period. During its most flourishing condition, in the course of the preceding century, the inhabitants are supposed to have amounted to 100,000; successive public calamaties, however, reduced them to 25,000, or 26,000, in 1781. In the year 1798, by an actual enumeration, the population was found to amount to 45,000 souls; but so rapid has been the increase of late, that it is now computed at between 80,000 and 90,000. The cause of so unexampled an augmentation, is ascribed to the growing prosperity of the island in general, the extension of commerce, circumstances which have driven many families from agricultural pursuits, and particularly to the presence of the British forces. This is the only place in the island where there are any Jews, as that nation has been proscribed since the year 1492, when they were expelled from the Spanish dominions.

Messina is a place of great antiquity, first known by the name of *Zancle*, or *Zanclea*, from one of its founders; though some etymologists maintain that this is a Greek word, characteristic of the shape of its harbour, which resembles a sickle. A new colony having come hither from *Mycene* in Greece, it was thenceforward called *Messana*, and at a later date was the scene of sanguinary hostilities between the Romans and Carthaginians. Since that time it has participated in the general fortunes of the island. But in modern history it has been chiefly celebrated for its misfortunes. When in a very prosperous condition, the plague, introduced by a vessel from the Levant, in 1743, swept away 35,000 souls in the course of a few months; and before having completely recovered from this disaster, the inhabitants were visited by another awful calamity. At noon, on the 5th of February, 1783, a long thick cloud was seen on the opposite shore of Calabria, which was instantly followed by a hollow subterraneous rolling under the city; and, amidst a torrent of hail and rain, accompanied by loud peals of thunder, an earthquake shook it to its foundations. The inhabitants fled from their houses to the squares and open places; while a suffocating smell of sulphur escaped from the earth, opening in fissures under their feet. Incessant undulations continued during several successive hours, when at length a tremendous concussion, at about 7 or 8 o'clock of the subsequent evening, completed the overthrow of the more solid edifices, which had resisted the feeble shocks preceding it. Numbers of the citizens were overwhelmed by the ruins; many, in the scene of terror and dismay, hurried to the quay to get on board of the vessels lying there; some sought refuge in the country; but others, more intrepid, disregarded their own safety, to rescue their weaker relatives from the walls and rafters which were crashing around them. Half of the whole city was now levelled with the ground; one quarter of it rendered ruinous; and the remaining portion greatly damaged. Churches, convents, colleges, and palaces, all had fallen; the palazzata, almost through its entire length, was injured; houses, fountains, and statues were demolished; and scarcely any, excepting those structures occupying the higher grounds, were spared. To aggravate the public calamity, conflagrations succeeding the earthquake, ravaged the city during seven days; and the licentious, availing themselves of the general disorder, pillaged and murdered the defenceless without remorse. Yet amidst such a field of desolation, only 700 or 800 of the inhabitants perished, owing to the survivors having had time to quit their houses before they tumbled, and from so many having been driven to the country by their first apprehensions. Temporary huts and barracks were erected for those preserved; and the public magazines having been saved, these, along with immediate importations of provisions, alleviated their distresses. But such were their sufferings, that even with the lapse of six years they had not fully recovered from the horror and stupefaction occasioned by the disaster. A long time elapsed before the earth recovered its stability. Above 200 shocks were felt within the two months following; and the city, since that time, has been repeatedly threatened with another convulsion. At present, most of the ruins are removed, and new edifices supply the place of many that were destroyed.

During part of the late war, Messina was the head quarters of the British army, amounting, in the year 1806, to 10,000 men, sent for the protection of Sicily; and a flotilla lay in the harbour when Murat collected a force on the opposite side of the Straits. The inhabitants, nevertheless, are accused of having engaged in a conspiracy with the other islanders, to betray the British army, which was detected in the year 1812, and many of the ringleaders punished by the sentence of a military commission, composed partly of British, and partly of Sicilian officers. East Long. 15° 40′, North Lat. 38° 10′.

MESTA. See Spain.

METALLURGY, in its most extended signification, means the working of metals in every different way. It therefore includes gilding, parting, smelting, assaying, &c. in its more limited sense, however, it is used to denote the process of smelting, or the separation of metals from their ores, for the purposes of art, and the assaying of these, with the view of ascertaining their value. In this last sense it is here used.

Almost all the ores employed in metallurgy, are embedded in quartzy matter, from which they must be freed as much as possible, before they are subjected to the process of smelting. The methods followed in the reduction differ in the different ores.

The assay of ores is performed in two different ways, with the view, either of ascertaining the quantities of all the different substances which the ore contains, or only the proportion of the metal for which it is wrought. The latter of these is used in the arts, and is more properly termed assay, the former being called analysis.

When assaying an ore, for the purpose of ascertaining with tolerable precision the quantity of metal contained in a large collection of it, we must take pieces from different parts of it, and put these together, by which we procure a mixture, containing the mean quantity of metal in the different pieces. In all the different assays, the ore must be reduced to powder, or to small fragments before it is weighed, and care must be taken that none of it is thrown out of the vessel during the operation, and the product should not be removed from the crucible till it is quite cold. If the assay be well performed, the metallic button obtained, will have a convex surface, and will be of uniform density; the scoria will be compact, and without the admixture of metallic grains. We must never trust to one assay, but repeat the process several times, and, as in general there will be a slight difference in the results, we must take the mean of the whole as the quantity of metal in the ore.

In the following article, under each metal will be included the different methods practised in the smelting of its ores, and the assays which are performed on them, with the view of ascertaining the quantity of metal in them for which they are used. The metals employed in the arts, are

Iron.

For the reduction of iron ores, see Iron.

Assay. The assay of iron ores differs a little, according to the ore employed.

The common magnetic iron-stone is assayed by mixing it, when reduced to powder, with about twice its weight of a flux, composed of 1 of charcoal, 6 of chalk, and 8 of bottle glass. The mixture must be exposed to a very strong heat in a blast furnace, for about an hour, after which the iron will be found at the bottom of the crucible. If the ore contain sulphur, it must be roasted previous to its mixture with the flux.

The other ores of iron are assayed nearly in the same way. When very little earthy matter is present, they may be reduced by using charcoal without the flux; and if the ore contain much calcareous matter, the quantity of chalk in the flux may be diminished.

Gold.

Gold is always found in its native state, generally alloyed with silver and copper, and occasionally with tellurium. Some of the iron pyrites, and galena also, contain a sufficient quantity of this metal, to make them valuable as ores of gold.

When gold is found alloyed with silver mixed only with stoney matter, the method of extracting the metal is very simple. In working a mine containing gold in this state, the whole of the matter procured from the vein, is collected and broken into pieces about the size of a nut, which are arranged into heaps, according to their richness. The small fragments, and the refuse of the different processes, are also collected and arranged according to their value. The quantities thus procured, are afterwards broken into smaller pieces, and freed as much as possible from impurities. They are then reduced to powder, and made into a thick paste with salt and water. Mercury is now squeezed through a leather bag on the mixture, and as the metal flows in, in very minute globules, it is intimately blended with it by means of wooden spatules. When the requisite quantity of mercury is added, the whole is beat together, and kept at about the temperature of boiling water, for two or three days, by which the union of the gold and mercury is promoted. The earthy matter is then carried off by levigation, and the superfluous mercury removed, by squeezing the amalgam through a leather bag. What remains is subjected to distillation, by which the mercury is driven off, and the gold is obtained, perhaps containing a little silver. The method of separating these will be explained when treating of silver.

When the other ores containing gold are found in the same mine, they are carefully separated from the former, and are collected into heaps, arranged according to their richness and hardness. The process for extracting the gold from these, is much more complicated than that just described.

In extracting gold from these ores, the first part of the process consists in separating the metallic from the earthy substances. For this purpose the ore is reduced to powder, in a *stamping-mill.* The stamping-mill consists of a large cistern, in which the ore is placed, and through which a stream of water passes, and of the stampers, which are heavy beams of wood, terminated below by iron, and which are moved upwards and downwards by a water-wheel.

Great attention is necessary in this part of the process, that the whole of the foreign matter which can be removed by the hand, be separated before the ore is put into the cistern, and that the proper force be applied, according to the hardness of the ore. This is easily regulated, by increasing or diminishing the depth of the layer of ore in the cistern; hence the quantity of ore put in, is always inversely as its hardness; accordingly, when the layer of ore is thin, the stampers have a greater fall, and the ore is thus subjected to greater force. It is necessary also, that the ore be placed in a particular way. The layer is so formed, that below the two outer stampers it is thickest, and gradually diminishes towards the centre. When the ore is reduced to powder, and sufficiently fine to float in the water, it is carried off, by the stream of this fluid into vessels, in which it is deposited; the heaviest being deposited nearest the cistern. Particular care is also necessary, that the stamping be not done too rapidly, otherwise the stampers are apt to throw up pieces of the ore, not sufficiently pulverised, which flow out with the fine powder, and prove detrimental in the subsequent part of the process. The stamping should therefore be performed slowly, and the fresh ore, as it is put in, must be placed below the middle stamper, where it is subjected to the greatest force, and from which it is thrown under the other stampers.

The vessels into which the water flows from the cistern, are arranged in a particular way, and a great deal depends on the performance of this part of the process; for by altering the velocity of the current of water in them, the rapidity with which the powder is deposited also alters. The vessels are of different dimensions, that nearest the cistern being about 12 feet long, and 9 inches broad, and as many deep. The others gradually enlarge as they retire from the cistern. They also vary in their inclination, the first having a slope of about 3 inches, the second about 1 inch, the third and fourth about ½ an inch, and the fifth and sixth being level. Each vessel is furnished with a groove at the extremity farthest from the cistern, into which pieces of wood are placed, varying in height, according to the quantity of ore that is collected in the vessel, and each vessel communicates with that beyond it.

When the water flows from the cistern into the first vessel, the heavy part of the ore is deposited and collected where the wood is put into the groove; as the powder reaches the top of this, another piece is put over the former, and so on till the vessel is nearly filled. When this is the case, the water is allowed to flow into the second vessel, and from this, when full, into the third, by which means the different parts of the ore are collected, according to their specific gravity in the different vessels. The parcels of ore thus procured, are still farther freed from impurities by washing. For this purpose, each parcel is put into a wicker basket, into which a stream of water slowly flows, and which, as it issues, is received on inclined tables, grooved in various directions. By this means, the ore is still farther separated, according to the specific gravity of the particles, the heaviest being deposited in the upper groove. Some of the ores of gold are subjected to another washing, in a vessel similar in shape to a fire-shovel, called a *buddle.* This is immersed in water, and a particular motion is given to it by the workman, by which the lighter particles are thrown out, and the heavy metallic matter is left in the buddle. If the gold procured by this process be mixed only with earthy matter, it is subjected to amalgamation, as already described; or it is fused in crucibles with nitre. If, however, it be mixed with inflammable matter, as sulphur, it is roasted, by which the sulphur is expelled. It is then mixed with lime and galena, in quantity proportionate to the gold contained in it, which is ascertained by assaying it, and kept at a red heat, in a reverberatory furnace, till part of the sulphur is expelled. The heat is then increased, till the whole becomes fluid, after which it is poured into moulds of sand. The product of this operation consists of scoria above, and beneath of a metallic matter, composed of gold, silver, copper, lead, iron, and a little sulphur. By repeated fusions the gold is obtained, alloyed only with silver, copper, and lead, from which it is freed by the process of refining.

The refining of gold is performed in different ways, according to the metals with which it is mixed. Of these the most common is *cupellation*, or *testing*, the former term being employed when the operation is performed on a small, the latter, when it is practised on a large scale.

Gold is one of the metals which is not oxidated by heat and air, while the other metals, with which it is usually alloyed, except silver, pass into the state of oxide, at a high temperature. This constitutes the process of cupellation, which is merely the separation of the precious from the baser metals, by means of oxidation. When, however, the base metals are in small quantity, compared with that of the gold, the oxidation is not complete; but if a metal, which is easily oxidated, and the oxide of which is very fusible, be added to the alloy, the oxidation of the base metals is promoted, and they are completely separated. The metal always employed is lead, and the quantity added depends on the proportion of gold which the alloy contains. (For a particular account of the process of refining, see *Silver*, in this article, p. 77.)

If lead be the only metal with which the gold is alloyed, the process of cupellation is sufficient for its purification; if, however, which is usually the case, silver and copper be also present, other methods are necessary to free it from these metals. When copper only exists, the gold is mixed with silver and lead, and then subjected to cupellation, by which the base metals are removed, but the gold still retains the silver; it is necessary, therefore, to have recourse to means for separating these two metals. When the gold amounts to about one-fourth of the alloy, the process is carried on by means of nitric acid. Silver is easily acted on by nitric acid, while gold is not; if, however, the gold exceed what is stated above, the whole of the silver is not dissolved; it is necessary, therefore, for this process, that the alloy employed do not contain more than one-fourth of gold; if it do, it must be fused with poorer alloy, *i. e.* alloy which contains a great deal of silver. When in this state, it is poured into cold water, by which it is reduced to powder, or *granulated*, as it is called. The granulated alloy is then put into *parting-glasses*, which are vessels of a pear-shape, about 12 inches long, and 7 wide at the bottom. Into each of these about 40 ounces of the alloy are put along with nitric acid, so that the acid cover the alloy to about the depth of two or three inches. These are gently heated on a sand bath, and when the action has ceased, the solution is poured off, and another quantity of acid is added, and the process is repeated a third time, which is, in general, sufficient to dissolve the whole of the silver. The last portion of acid, as containing little metal, is used as the first quantity, in the next purification; the two first are decomposed by the immersion of copper plates, by which the silver is deposited in the metallic state. The gold left after the action of the acid is washed with warm water, till the fluid which comes off does not alter the colour of a piece of copper, and is then fused in a crucible with nitre and borax, by which all impurities are removed.

When the proportion of gold in an alloy is much smaller than that mentioned, a different process is sometimes followed for separating it from the silver. For this purpose, the alloy is melted and granulated. About seven-eighths of it are then mixed with about one-eighth of the flowers of sulphur, and the mixture heated in a covered crucible, first slowly, and afterwards till the whole is brought into fusion, in which state it is kept on the fire for about an hour; one-third of the alloy kept out is then added, and thoroughly stirred with it by means of a wooden rod, and the whole is again heated for about an hour. Another third of the alloy is afterwards mixed with it, and after a similar operation, the remaining quantity is added, and the mixture kept fused for about three hours, during which it is frequently stirred. It is then, when the surface has become quite white, poured into cones greased in the inside. When it is solid, it is found to have separated into distinct parts, the upper is sulphuret of silver, the lower is a metallic button, composed of gold and silver. If the former contain gold, it is exposed to heat in an open crucible, by which part of the sulphur is dissipated, and the silver set free, unites with the gold, and collects at the bottom of the vessel as the matter cools. The metal thus obtained is repeatedly subjected to the same process, till the alloy procured contain a large enough quantity of gold to admit of its separation from the silver, by the process of parting already described.

Gold is occasionally deprived of the baser metals by the use of sulphuret of antimony, sulphur having a stronger attraction for the other metals than for antimony, while it does not combine with gold. To purify gold by this means, it is necessary to employ crucibles which are not porous. To render them so, they are soaked in oil, and then besmeared in the inside with pounded borax. The gold alloy is fused in these, and about twice its weight of sulphuret of antimony is added in successive portions, taking care that the mixture does not swell and flow out of the crucible. If the quantity of gold be very small, the sulphuret must be previously fused, with an additional quantity of sulphur, so that too much antimony may not be used. When the whole of the mixture is in a state of fusion, and when it sparkles, it is poured into greased cones, which must be struck gently as the matter consolidates, to cause the gold to fall to the bottom. When cold, the gold is found united with the antimony, and also with a little of the alloying metals; it must, therefore, be subjected to the same process, with an additional quantity of sulphuret, a second and a third time, by which the whole of these are removed. The next part of the process is to separate the gold and antimony. For this purpose the alloy, reduced to fragments, is fused with one-fourth of its weight of sulphur, in a covered crucible, by which the greater part of the antimony quits the gold, and unites with the inflammable body. The fused matter is then poured into greased cones; and when cold, the gold still retaining a little antimony, is collected at the bottom. To free it from this it must be fused, and a stream of air made to pass over it, by which the antimony is oxidated, and dissipated by the heat, and the gold is left. If not quite purified by this process, it must be fused with a little nitre, which will oxidate the antimony, and leave the gold pure. The sulphuret of antimony, formed by the fusion of the alloy and sulphur, contains a small quantity of gold. To obtain this from it, it must be fused with about one fifth of its weight of iron filings, which will unite with the sulphur; the antimony will combine with the gold, and may be separated by the method above described.

The process of purifying gold by *cementation*, is still practised in some particular cases. It consists in beating the alloy to thin plates, and placing these in alternate layers, with a cement composed of 1 of nitre, 2 of calcined green vitriol, and 2 of pounded tiles, made into a paste with urine, taking care that there be cement at the top and bottom of the vessels. These are placed in a furnace, and kept at a heat, below the melting point of gold, for 24 hours. The gold is then removed, and boiled, first in water, and afterwards in nitric acid, by which the foreign matter is washed off. The plates are repeatedly subjected to a similar operation; and in this way a great deal of the alloying metals are removed by the nitric acid, set at liberty from the nitre by the action of the acid of the salt of iron on it. The superiority of this process depends on the nitric acid, at the temperature to which it is exposed, acting on silver and copper, though in small quantity, which is not the case when the liquid acid is boiled on the alloy; it does not, however, afford the gold pure, it is therefore practised only when this metal is not required very fine, as in the formation of trinkets.

Assay of Gold Ores.—As gold ores contain in general but few ingredients, their assay is easily performed. For this purpose the ore is reduced to powder, and mixed with 1 of fused borax, and 4 of sub-carbonate of potassa, and subjected to heat in a crucible. When fused, it is poured out, and if any remain in the vessel, it must be removed by muriatic acid. This, with the fused matter reduced to powder, is digested in muriatic acid, to which from time to time a little nitric acid is added. When the action ceases, the solution is poured off, and the residue is well washed with water, the washings being mixed with the solution. To the solution, neutralized by a fixed alkali, green sulphate of iron is added, as long as it causes any precipitation; the precipitate, after being washed, is fused in a crucible with a little nitre; and affords gold in a state of purity. If the part of the ore not acted on by the acid become black by exposure to light, it contains silver. To procure this, it must be fused with about thrice its weight of sub-carbonate of potassa, by which the silver is reduced and is mixed with the earthy matter. By washing the product in muriatic acid, the latter is separated, and the silver is left.

Iron pyrites containing gold is analysed by digesting the ore in muriatic acid, to which a little nitric acid is added. What is left must be roasted to drive off the sulphur, and again digested in acid. The solutions obtained must be neutralized by potassa, and proto-nitrate of mercury is added. The precipitate thrown down is then fused with nitre, by which the gold is procured. If silver be also contained in the ore, it is obtained by treating that part of it not acted on by the acid with sub-carbonate of potassa and muriatic acid, as above described. Galena, containing gold, is analysed by digesting it in nitro-muriatic acid, evaporating the solution, and afterwards adding proto-nitrate of mercury. The insoluble part, when treated as above, will yield the silver, if any exist in the ore.

The assay of gold, as performed on its alloys, will be given when treating of assay of silver.

Silver.

Silver is obtained not only from the proper ores of silver, but likewise from some of the ores which are wrought to yield other metals. Of these the principal are the ores of lead.

Reduction of Ores.

Two methods are practised for procuring silver, the one is by *amalgamation*, the other is by *fusion*. The former is followed when the ore is rich in silver, the latter when it contains little of the precious metal.

Amalgamation. The ores which are subjected to the process of amalgamation contain, in general, besides lead and copper, a small quantity of iron pyrites; if they do not, some of this is usually mixed with them, by which the extraction of the silver is facilitated. The ore, after being freed as much as possible from its stony ingredients, is mixed with common salt, in the proportion of 8 or 9 per cent. if the ore contain 8 oz. per quintal; and 10 or 12 per cent. if more silver be contained in it. It is then exposed for some hours on the floor of a reverberatory, till the vapour cease to come off; the mixture being frequently stirred to expose the whole of it to the flame. If, when removed, too little or too much of the salt have been added, (which the workman by experience easily knows,) the proportions must be adjusted, by adding either more of the salt or of the ore, and the mixture is again roasted in the reverberatory. During this part of the operation, the sulphur of the ore is partly dissipated in the form of sulphurous acid, part of it in the state of acid combines with the alkali of the salt, and the muriatic acid set free unites with the silver. When the matter is cold, it is reduced to powder in a mill, and then amalgamated with about an equal quantity of mercury. The amalgamation is performed in barrels, which are made to revolve, or in tubs which contain an apparatus for keeping the mixture in constant agitation. The mixture is put into these vessels, and made into a thickish paste with water, and kept agitated for about two days, and after the amalgam has fallen to the bottom, it is withdrawn through an aperture in the lower part of the vessel. What remains is washed, by which more of the amalgam is got from it, and the residual matter, if the ore contained a great deal of silver, is again roasted with about 3 per cent. of sulphur, and subjected to a similar process, by which the whole of the metal is extracted. The amalgam procured by these different operations is freed of its superfluous mercury, and is then subjected to distillation, by which the whole of the mercury is expelled and the silver is left; retaining, however, a little copper, which is removed by cupellation.

Fusion.—The ore generally subjected to the process of fusion is lead glance, which almost always contains a small quantity of silver. When lead mines are wrought on account not only of the lead, but also of the silver, the earthy matter mixed with the ore is considerable, and the quantity of silver is very various in different mines. In some, as those formerly wrought in Yorkshire, the silver amounted to about 230 oz. in the ton, while the Durham and Westmoreland mines afford only 17 oz. per ton.

The first part of the process for procuring silver from these ores consists in stamping and washing, as has been already described, after which the substance contains silver, lead, iron pyrites, blende, and earthy matter. The ore is then roasted in a reverberatory to drive off the sulphur, taking care that the heat be not so high as to fuse it, and that when it begins to adhere together on the surface, it be well stirred. In about five or six hours, the flame from the ore changes from blue to white, charcoal in powder is then thrown in, by which part of the lead ore is reduced, and collects at the bottom; when a sufficient quantity is formed, quicksilver is mixed with the scoria to thicken it, and the fused metal is drawn off. After this, the heat is continued, and the metal, as it is formed, is repeatedly taken out, the temperature being increased towards the end of the process, to cause the scoria to become more liquid, so as to allow the metal to fall through it. The metal, as it is collected, is covered with charcoal; and the scoria which is formed is removed. It is then covered with saw-dust, pieces of wood, and a little resin, and constantly stirred; and when the flame ceases, it is poured into moulds. The scoria procured in the different operations is afterwards heated in a blast furnace, to procure the lead from it.

The lead containing the silver obtained by the above operations, is then subjected to the process of refining, which is the same as cupellation, only performed on a large scale. For this purpose, a reverberatory furnace is employed, but the process differs in different places, owing to a difference in the nature of the ore. In England, the cupel, or vessel in which the refining is performed, is composed of 6 parts of bone ashes, and 1 of fern ashes, made into a paste with water. In the centre of this there is a shallow cavity, for the reception of the metal, and at one end there is a hole for the escape of the litharge formed during the operation; the litharge flowing into this, along a groove made in the cupel. When the cupel is heated, the metal is put in through an aperture in the furnace, and a stream of air is made to play on it, by which the litharge is formed, and escapes along the groove. As this groove is destroyed, the litharge is made to run along another, and in this way the whole of it is withdrawn. The metal in the cupel is again subjected to a similar operation, after which it is poured into moulds, and formed into ingots.

In other places, the lower part of the reverberatory is covered with wood ashes and clay, so as to form a cupel. On one side of the furnace there is a hole for the exit of the litharge; and on the opposite side is another for the admission of air to the surface of the metal, which is introduced through an aperture above, to which a cover is adapted. After the lead is melted and brought to a red heat, the blast of air is admitted, and the scoria as it collects is removed. When the litharge is formed, the heat is increased, and the quantity becomes greater, and is withdrawn through the opening in the furnace. At the same time some lead is volatilized. Towards the end of the process, the litharge which comes off contains a small quantity of silver, and is therefore kept separate from the rest. After the whole of the litharge is removed, and the surface of the metal in the furnace becomes bright, a quantity of water is poured on it, to prevent the metal from spirting, which it is apt to do when congealing. The metal thus obtained, is subjected to a similar operation for about five hours, in a smaller furnace, and at a higher temperature, by which it is freed from the lead.

Silver is also occasionally procured from the silver ores by the process of fusion. The process, as carried on in France, consists in mixing the ore (which contains native silver, sulphuret of silver, iron pyrites, arsenic and cobalt,) with lime, the scoria of a former operation, and slag from an iron furnace, to make it more fusible. Galena and litharge of a previous process are also added. These, when mixed, are exposed to heat in a blast furnace, along with charcoal, by which a metallic matter, composed of silver and lead, is obtained. This is again fused with litharge, and the metal procured is afterwards subjected to the process of cupellation, at a temperature higher than that in the other instances, owing perhaps to the presence of iron, which occasions a considerable loss of silver.

When the ore also contains copper, a different process is followed for procuring silver from it. The ore is mixed with another ore, containing silver, iron, and sulphur, and with the scoria of a former process. The mixture is fused in a blast furnace, and the sulphur unites with the silver, with the lead, and with the copper. The matter, during cooling, separates into two parts; that below, amounting to about one-fourth, is the silver mixed with lead, copper, iron, sulphur, and arsenic, and is roasted to expel the two last ingredients, and to oxidate the iron. It is then mixed with about one and a half of rich ore, and some scoria, and is fused. The metallic matter thus obtained is again roasted, and fused with about one-half of litharge, and as much scoria. When cold it separates into three parts, 1st, lead mixed with silver; 2d, copper and silver; 3d, scoria, also containing copper. The second of these is melted with lead and copper scoria, and afterwards with litharge and scoria, by which the silver unites with the lead. Should the whole of the copper not be removed, the metal must be repeatedly fused; by which not only the copper, but the other impurities are, separated. The scoria of this process is kept and mixed with ore in other operations.

Eliquation.—Silver is also sometimes separated from copper by the process of eliquation. The eliquation of silver ore is performed by melting the alloy of copper and silver mixed with lead, or with litharge and charcoal. For this purpose a blast furnace is employed, having its bottom lined with charcoal, beat together, and forming an inclined plane. When the furnace is kindled, it is filled with charcoal, to which some scoria is added, which, by the heat, is fused, and adheres to the sides of the furnace. A quantity of lead and of the alloy is then thrown in, and afterwards litharge mixed with charcoal. Another quantity of the alloy and litharge is then added, and lastly some lead. By the application of a strong heat, these substances are fused, and the litharge is reduced by the charcoal; the melted matter collects at the bottom, and is drawn off into moulds lined with clay, and previously heated. While the metal in these is in a state of fusion, a bar of iron bent at the end is plunged a little way into it, by which it is removed, when cold, from the mould.

The loaves are then placed in a furnace, on bars of iron, and separated from each other by bricks. By the application of heat, the lead is melted, and runs along a groove in the lower part of the furnace, carrying with it the silver. In this part of the process, great care must be taken not to raise the heat too high, otherwise part of the copper will be melted, and run out with the lead. When the lead ceases to flow from the loaves, the fire must be stopped, after which the copper is left in the state of a reddish spongy mass, still retaining a minute quantity of silver, perhaps not exceeding half an ounce in the 100 pounds; they are therefore exposed to heat, by which a metallic matter exudes from them, consisting of silver, lead, litharge, arsenic, and scoria, and if the heat has not been cautiously applied, of some copper. When the metal which exudes has a reddish colour, the process must be stopped. The metal procured by this operation is freed of some of its impurities by washing, and is then subjected to cupellation. The copper left in the furnace is nearly pure.

In the first part of this process, the heat must be less than what is necessary to melt the copper; and by using litharge and charcoal instead of lead, the operation is expedited, because the litharge, before it is reduced, proves a good flux. If lead be employed, it should amount, at least, to two and a half times the quantity of copper, otherwise the whole of the silver will not be extracted. On the contrary, it should not exceed four times the quantity of copper, otherwise part of that metal will be carried along with it and the silver; the proper proportions therefore are between three and four parts; the exact quantity will of course depend on that of the silver. It is necessary also, that the ore contain a certain quantity of silver, otherwise the process is not complete. From one to three-fourths per cent. seem the best Should, therefore, the different ores have different quantities of this metal, they must be mixed, so as to get a collection which contains the proper proportion of it.

In Germany, where the copper alloy contains about three-fourths per cent. of silver, the proportions of the substances employed, are three of the alloy, and eleven of lead. When the alloy does not contain so much silver, about ten of lead are used. If, instead of lead, litharge be employed, 120 of the latter must be used for each 100 of the former that were requisite.

Assay.—The word assay, in its extended sense, means the analysis of the different metallic ores, with the view of ascertaining the quantity of valuable materials which they contain; in its more limited acceptation, however, and in which sense it is usually employed, it signifies the process followed for ascertaining the quantity of gold and silver, either in an ore, or in alloys of these metals. In a still more limited sense, it applies only to the analysis of the latter, as in determining the quantity of gold or silver in plate, coins, and articles of jewellery. The assay of gold and silver alloys requires to be performed with very great care, as it is done on a very small scale. Before a piece of plate can be stamped, it must be assayed. For this purpose, before it is finished, it is taken to the assay-master, a person in the pay of the Company of Goldsmiths, who scrapes off a small quantity of it at different places; these he collects together, and sets aside for the assay. The same is practised with the other alloys submitted to his examination.

When treating of gold, it was mentioned that it and silver resist the action of heat and air, while the other metals with which they are alloyed, are oxidated at a high temperature. On this depends the assay of gold and silver alloys. For the complete success of this process, it is necessary that the quantity of base metal be large, otherwise the attraction between the noble metal and it prevents their separation. For this reason, a quantity of lead is always mixed with the alloy. The separation of gold and silver from other metals, by means of lead, is called *cupellation*, and the process is performed on a *cupel* placed in a *muffle*. A cupel is a dish of a circular or pyramidal shape, made of bone-ashes, and having a small depression on its upper surface, into which the alloy is put. A muffle is a vessel made of earthen ware, flat below, and arched above, open at one end, and shut at the other, and at the sides, except where it is perforated by small holes. The furnace employed in cupellation is one in which a strong heat can be excited, and having a hole in its sides for the admissinn of the muffle. When the cupellation is to be performed, the muffle is placed in the furnace, to which it is generally secured by luting The furnace is then kindled, and the muffle and cupels are slowly heated. When these are red-hot, the alloy, beat out to a thin plate, and rolled up in a sheet of lead, obtained by the reduction of litharge, is put into the cupel. To prevent the air which enters the muffle from lowering the temperature of the metal, a quantity of burning charcoal is put at its mouth, by which the air, previous to its entrance, is heated. After the metal is put in, it very soon melts, and emits white fumes, and a quantity of a reddish substance is formed, which is absorbed by the cupel. This is the lead oxidated, carrying along with it the metal with which the silver is alloyed. As the process proceeds, the fused metal acquires a globular form, and its surface is studded over with melted litharge; at last the silver acquires a beautiful brilliancy, which is a proof that the cupellation is finished. The cupel is then allowed to cool slowly, to prevent the contraction of the outer parts of the metal from scattering about the internal unconsolidated portion. The silver is then taken out and carefully weighed.

It is of material consequence to know the exact quantity of lead that must be added to the alloy, for, if too little be used, the whole of the base metals are not extracted, which is known by the metal left in the cupel being flat, of a dull colour, and adhering to the dish. If too much lead be employed, the litharge formed carries along with it a minute quantity of the noble metal; accordingly, if the litharge be again subjected to cupellation, it leaves a little silver on the cupel. To ascertain the quantity of lead requisite, *touch-needles* were formerly employed. These were bars of alloys, containing different known quantities of silver and copper, with which the alloy to be assayed was compared. This mode is however almost abandoned, the assay-master trusting to the appearance of the alloy, the ease with which it is cut, its malleability, and the colour of its surface, when heated. It is of very great importance also to attend to the heat required. If the heat be too strong, part of the silver is volatilized; if too low, the litharge is not absorbed by the cupel.

If the process of cupellation be well performed, the button of metal left adheres slightly to the cupel, its surface is brilliant, and quite clean, and it has a globular shape The silver also sometimes presents a laminated structure, which, when viewed through a microscope, appears composed of scales of a pentagonal shape. This is a good test of the purity of the metal; for when any of the alloying metal is left, the surface is quite smooth. Where great delicacy is required in the assay, two portions ought to be subjected to cupellation at the same time; and should the results not agree, the operation must be repeated.

The assay of silver ores, with the view of ascertaining the quantity of silver, is performed nearly in the same way as the assay of the alloy. For this purpose the ore is roasted, and then mixed with litharge, and quickly fused. The product is then fused with black flux, by which the litharge is reduced, and the lead falls to the bottom, carrying with it the other metals. The metallic button is afterwards mixed with the proper quantity of lead, and subjected to cupellation, by which the silver is obtained pure. Should the ore contain gold, this will be found along with the silver. These must therefore be separated by the process of *parting*, described under the assay of gold.

The analysis of the ores of silver, with the view of ascertaining the quantity of all the ingredients, is performed chiefly by the action of nitric acid. That just described is, however, the one usually followed in the arts.

Assay of Gold Alloys.—The affinity between gold and silver is so strong that they cannot be separated entirely from each other by cupellation, unless a quantity of silver be added; besides, gold is frequently alloyed with copper and silver, or with silver alone, as in some coins and trinkets. This makes the assay of gold more complicated than that of silver, as the gold and silver must also be separated from each other. In general, the silver added to the alloy amounts to about three times the quantity of gold, though some recommend that only twice the quantity should be employed.

The alloy being mixed with the requisite proportions of lead and silver, is placed in a muffle, and the cupellation is performed in the same way as with silver. When the process is finished, the button of metal is taken out, and kept in a state of fusion in a crucible, for some time, by which the whole of the lead is expelled. It is, when cold, beat into a plate, again made red hot, and slowly cooled. It is afterwards extended into a thin leaf, between steel rollers, and coiled loosely up, in which state it is submitted to the process of *parting*, by which the gold and silver are separated.

In the cupellation of gold, the heat required is stronger than is requisite for that of silver; and there is little risk of making it too high, as the alloy of gold and silver is not volatilized.

As in the cupellation of silver, it is necessary that the due proportion of the metals with which the alloy is to be mixed, be employed. This is ascertained in different ways. A tolerably accurate idea of the quantity of gold in an alloy is acquired by the use of *touch-needles.* Of these there are four different kinds: 1*st*, gold alloyed with silver; 2*d*, gold and copper; 3*d*, gold, with two of silver and one of copper; 4*th*, gold, with two of copper and one of silver. These have different quantities of gold alloyed with them; they are not, however, much employed, more particularly those containing copper, as the colour communicated by this metal to gold does not differ much from that of the different kinds of copper.

Another method by which the quantity of gold is estimated, is by the streak which the alloy gives on the darker sorts of basalt, or on black pottery. The streak is compared with those given by touch needles, which is, in general, made more distinct by the stone being previously wetted. Occasionally a drop of nitric acid is put on the streak, and by the effects produced on it the quantity of gold is estimated. By the different colours communicated, the workman acquires, by experience, an idea of the quantity of gold present. When the proportion of gold is large, it is necessary to add a little muriatic acid to the nitric acid, otherwise the streak is not affected; the gold seemingly protecting the other metals from the action of the acid. According to Vauquelin, the best acid is composed of 98 nitric acid, of specific gravity 1340, 2 of muriatic acid 1173, and 25 of water. When this acid is used, it must not remain long on the streak.

The quantity of lead added to the alloys of silver and gold is differently stated by different assayers. According to the experiments of Tillet, Hellot, and Macquer,

1 copper,	3 silver, require	40 of lead.
1	5	48
1	23	96

The quantity of lead necessary increasing with the silver. Others recommend a smaller quantity of lead. The proportion of lead added to gold alloys is nearly the same.

After the cupellation, the product must be subjected to the process of parting, which is nearly the same as has been described, when explaining the methods practised in the purification of gold. For this purpose, the coil of metal is put into a pear-shaped glass vessel, with two or three times its weight of slightly diluted nitric acid, and heat is applied, by which the acid acts on the silver, and leaves the gold. When the action has ceased, which is known by the cessation of the red fumes, the coil is left corroded, but unbroken; the fluid is then poured off, another quantity of acid is boiled on it for a few minutes, and again decanted off; the vessel is then filled with water, and inverted, by which the coil falls out entire. The metal is afterwards subjected to a high temperature, by which it shrinks, and at last forms a button of resplendent gold; after which it is accurately weighed. The silver in solution is obtained by the immersion of a piece of copper, or by the addition of common salt, and fusion with pearl ashes.

It is of great consequence to be able, by easy methods, to separate gold from metals with which it is alloyed, when these are in large proportion, as in gold lace, and in gilded goods.

In separating gold from gold lace, the metal is fused and granulated, by pouring it into cold water. It is then treated nearly in the same way as has been explained for separating gold and silver, when the former is in small proportion.

For this purpose, a quantity of the granulated metal is mixed with one-eighth of flowers of sulphur, and kept in a state of fusion for about an hour, or till a kind of flashing appears on its surface. A quantity of the granulated metal, equal to about one-sixteenth part of the weight of that fused with the sulphur, is mixed with one-half its weight of litharge, and one-eighth of sandiver. The one-half of this is then added in successive portions to the fused mixture, which is well stirred on each addition. After this is added, the mixture is kept in the fused state for about ten minutes, and the upper part of it, which is silver in union with sulphur, is removed; the remainder is then poured into greased cones.

The portion removed is brought to a state of fusion, and the remaining half of the mixture of alloy, litharge and sandiver, is added in the same way as above described, and the product is poured into a cone.

At the bottom of the cones a metallic matter, composed of silver, with almost the whole of the gold, is collected. The substance above this still, however, retains a little gold; it is therefore again fused, and a small quantity of an alloy of equal parts of copper and lead is mixed with it, by which the whole of the gold is separated, or collected at the bottom of the cone into which the mixture is poured.

The different portions of metal procured are mixed and fused with one-eighth of lead, and treated in the same way as before, with sulphur, the mixture of alloy, litharge, and sandiver. What is collected is then fused with one-sixteenth part of sulphur, and kept in that state for half an hour. It is then poured into the cone, the silver and sulphur collect at the top, and the gold falls to the bottom. The sulphuret of silver must again and again be fused with sulphur, till the whole of the gold is separated. The gold collected is then fused with one-sixteenth of copper and granulated; the same quantity of sulphur is now mixed with it, and the mixture is fused for about a quarter of an hour, and then poured into a cone. The gold found at the bottom of this, is afterwards purified by sulphur and antimony, as already described.

In gilded copper goods the quantity of gold is very trifling, still, however, it is of consequence to separate it from the other metals; this is done in two ways: 1st, The gilded metal is fused and granulated, after which it is again fused, and flowers of sulphur are gradually added, till the whole becomes dark-coloured. When cold, it is reduced to powder, and amalgamated, as already described when treating of the ores of gold.—By this means the mercury combines with the gold, and leaves sulphuret of copper.

2*d*. The metal is brought to a state of fusion, and about an equal quantity of a mixture of litharge and sulphur, previously fused together, is added to it, and the whole is well stirred. Charcoal in fine powder is then thrown in, in small portions at a time, the mixture being constantly stirred with a copper rod. By this means the litharge is deprived of its oxygen, and the lead falls to the bottom, carrying the gold along with it.

The alloy of these metals is then subjected to the process of cupellation, by which the gold is obtained pure.

The quantity of silver on plated copper goods is often so great, as to make it an object of considerable importance to be able to separate this metal from the copper.

The process for separating silver and copper, when the former is in large quantity, has been already explained, but the proportion of the latter metal in plated goods is so great, that the silver cannot by these means be obtained from them, because they will not bear to be alloyed with a sufficient quantity of lead; recourse must therefore be had to other methods.

The best mode of separating copper and silver in plated goods was recommended by Mr. Keir. This gentleman discovered, that an acid composed of sulphuric and nitric acids did not act on copper, while it dissolved silver; he therefore applied this to the separation of these metals. For this purpose, 1 lb. of nitre is dissolved in 8 lb. or 10 lb. of sulphuric acid, with the aid of a gentle heat, in a glazed earthenware dish. Pieces of the goods are then thrown in, and the heat is raised to about the 200dth degree. When the whole of the silver is dissolved, the fluid is poured off, and the metal is precipitated by muriate of soda, and is obtained in the usual way; or the solution is diluted with water, and pieces of copper are immersed in it, by which the silver is precipitated in the metallic form, the diluted acid acting on the copper.

There is still another method of separating silver from copper, by means of the black oxide of manganese, when the silver is in large proportion.

The process consists in subjecting thin pieces of the alloy, surrounded by black oxide of manganese, to an intense heat, by which the metal is melted, and a black powder is procured. This is mixed with three times its bulk of pounded green glass, and again exposed to a strong heat, after which the silver is obtained pure at the bottom of the vessel. In the first part of this process the silver and copper are oxidated, and in the latter, the oxide of silver is reduced by heat alone, whereas the oxide of copper requires the presence of inflammable matter for its reduction.

Platinum.

Owing to the infusibility of Platinum, it is with great difficulty obtained in mass, so as to have it in a state fit to be wrought into different articles. The simplest and the cheapest method of working Platinum, is that practised in France. For this purpose, the grains of Platinum are mixed with an equal weight of white arsenic, and one-third of pearl-ashes. This is thrown, in successive portions, into a red-hot crucible, and well stirred with a platinum rod. When the whole is in a state of fusion, the crucible is removed from the furnace, and the mixture is allowed to cool. It is then taken from the pot, and bruised, and again subjected to a similar process. If after the second fusion the metallic matter is magnetic, it must be a third time treated in the same way.

After this it is mixed with an equal weight of white arsenic and a small quantity of pearl-ashes, and again fused in a flat earthern dish, in which it is allowed to cool.

It is next exposed to a heat in a muffle, sufficient to expel the arsenic, but not so high as to fuse the mixture. It is then, when hot, plunged into oil, and the exposure to heat and immersion in oil repeated, till the whole of the arsenic is driven off; the heat being gradually increased as the metal becomes less fusible. After the arsenic is expelled as completely as can be effected in this way, and the charcoal of the oil is consumed, it is digested in nitric acid, and then boiled in water to remove impurities. Several of the pieces of metal thus obtained are put together, and then exposed to a high temperature; in which state they are struck so as to make them adhere. The mass is then heated in a forge and beat on an anvil, by which one compact piece of metal is procured.

Platinum obtained by the above process is not pure; it contains arsenic, and the foreign ingredients of the grains, by which it is not so capable of standing an intense heat, or of resisting the action of chemical agents.

The other methods of obtaining platinum is by reducing its oxide obtained by dissolving the grains in nitro-muriatic acid, and precipitating by muriate of ammonia. For doing this, different processes are followed, though they all nearly agree with each other.

The best of these is, perhaps, that recommended by Mr. Cook.

It consists in exposing the precipitated oxide to heat, by which it is reduced, and the superfluous muriate of ammonia is expelled. About half an ounce of the spongy mass obtained is then put into an iron mould, and squeezed together by a wooden pestil. After this another half ounce is added, and in this way the operation is continued, till about six ounces are squeezed into the mould, which are still farther compressed by a strong iron screw, by which the whole of the air is expelled. It is then laid on burning charcoal, and exposed to a high temperature, and when hot beat on an anvil till it is of uniform density. After this operation, it is coated with a reddish crust, which is removed by covering it with borax and exposing it to a white heat; it is then washed with muriatic acid, which dissolves the foreign matter, and leaves the metal resplendent.

Platinum thus obtained still retains Iridium, which was precipitated from the nitro-muriatic solution; it is however sufficiently pure for the manufacture of utensils.

Before subjecting Platinum to any of these processes, the grains must be spread on a table, and a current of air from a bellows must be passed obliquely over them. By this the lighter particles, which consist of quartz and iron ore, are removed.

Occasionally the grains, as brought to Europe, contain a minute portion of gold. This may be got from them by treating them with a small quantity of nitro-muriatic acid. To the solution green sulphate of iron must be added, and the precipitate thrown down, purified by fusion with nitre and borax.

Copper.

The ores of copper generally employed for yielding the metal, are the sulphurets. These are wrought principally in Cornwall, in Anglesea, and in Hungary.

In Cornwall, the ores of copper are broken into small pieces, which are roasted in a furnace, somewhat similar to a reverberatory furnace, having a very long chimney to increase the heat, and to carry off the sulphur and arsenic with which the ore is roasted. During the roasting, which continues for about twelve hours, the ore is frequently stirred, so as to expose the whole of it to the flame. It is then put into a small furnace of the same form, and brought to a state of fusion, occasionally mixed with a little lime, to increase the fusibility. As the impurities collect at the top, they are raked out, and put into oblong moulds, in which they are allowed to cool. They then form a hard mass, which is used in building. The fused copper is drawn out through a hole in the lower part of the furnace, which was stopped by clay, mixed with a little coal, to prevent it from hardening. Fresh quantities of the roasted ore are then put in, and the process is in this way carried on for a considerable time.

The fused copper is conveyed into vessels suspended in a well, through which a stream of water runs. By this means the metal is reduced to the granular state. It is still, however, impure, being mixed with sulphur and arsenic.

To free it from these, the metal is repeatedly subjected to heat in a reverberatory furnace, and each time put into the well. During these processes, the slag collects on the surface of the fused metal; but as this contains a considerable quantity of copper, it is kept and mixed with the fresh ore, previous to its being put into the furnace.

The copper after this is kept at a low red heat for two days, and is then repeatedly fused, and cast into moulds about 14 inches in length. It is lastly put into the refining furnace, with a little charcoal, in which it is again fused. If after this it bear the hammer, it is fit for sale. When the fused copper is cast into the moulds, the purest part of it rises to the top, and may, when cold, be easily separated from the rest, by a blow of a hammer.

The copper ores of Anglesea are wrought nearly in the same way. The ore there, after being reduced to fragments, is put into a kiln, the flues of which terminate in a close chamber. Heat is then applied to the ore, and the sulphur, which sublimes, is carried through the flue, and condenses in the chamber. Fresh quantities of the ore are from time to time introduced, and the roasting is in this way kept up for several months.

The poorer part of the ore only is smelted in Anglesea, the richer portion being exported.

The smelting of the ore is carried on in a series of reverberatory furnaces, having tall flues to increase the draught. In these the ore mixed with a little coal-dust is fused, and purified by repeated fusions. By this means, twelve hundred weight of the roasted ore yield about one-fourth of a hundred weight of malleable metal; and each charge of the furnace, which is about twelve hundred weight, is finished in five hours.

In Hungary, the copper ore is treated in the same way, but the purification of the metal is accomplished by means of lead. For this purpose the metal is fused in a furnace, and about one-twelfth or one-fifteenth of lead is added, which forms a scoria along with the impurities of the copper. This is removed as it is formed, and the copper is left in its pure state, after which it is kept fused for some time. To ascertain when the whole of the impurities of the copper have been removed, the workman takes out a little of the melted metal on the end of a smooth iron rod. If the metal be pure, this falls off when it is dipt into cold water.

The purity of the metal is also known by the redness of the scoria, that of the impure copper being always dark coloured.

The thin sheets of copper used in the arts, are prepared when the metal is in a state of fusion in the furnace. For this purpose, when the whole of the impurities have been removed, the metal is allowed to cool to near its point of congelation. A wet broom is then drawn along its surface, by which means a thin layer of it is made to pass into the solid state. This is removed, and immediately plunged into water, by which it acquires a fine red colour; and the process is repeated till the whole is formed into thin sheets.

Copper, in a state of considerable purity, is sometimes procured from the springs which contain the sulphate of this metal. With this view, pieces of iron are put into the water, by which the copper is precipitated, owing to the superior affinity of the iron for the acid, aided, perhaps, by a galvanic action. When the whole of the iron is dissolved, the matter deposited is raked out, and is fused in a furnace, either alone or mixed with some of the poorer copper ore.

The deposit obtained in this way, when fused alone, commonly yields about 50 per cent. of copper.

Assay of Copper Ores.—The assay of copper ores may be made either in the dry or in the humid way; the former, however, when the sulphurets are employed, is imperfect; but when any of the oxides or carbonates are to be assayed, this method answers very well. The ore, after being reduced to powder, is mixed with charcoal, and exposed to a strong heat in a crucible, removing the scoria as it is formed. As the ore contains other metals besides copper, this process must be repeated several times before we obtain it pure. These ores are, however, seldom employed in metallurgy; it is necessary, therefore, to have recourse to other means, to ascertain the value of those which are used to yield copper. For this, the ore must be digested in muriatic acid, to which a little nitric acid is added, by which we obtain the different metals in solution. From this the copper may be procured, either oxidated or in the metallic form, the other metals in the solution being previously separated. Lead, if present, may be thrown down by sulphate of soda and iron, by the addition of ammonia in excess.

The quantity of copper may then be ascertained, either by precipitating it by sub-carbonate of soda, or, which is better, by the immersion of a plate of iron. For this purpose the solution is diluted with water, and a piece of polished iron is put into it, which soon becomes covered with a coating of copper, and as the decomposition proceeds, the metal is deposited in thin plates. When the whole of it is separated, it is collected, washed, and weighed. Towards the end of the process, the fluid should be heated, which favours the separation of the copper.

For obtaining the copper in this way, it is necessary that we have the metal dissolved in muriatic or sulphuric acid, for the nitrate of iron generated by the decomposition of the nitric acid solution is itself liable to be decomposed by heat. If, therefore, the copper be dissolved in nitric acid, the solution must be evaporated to dryness, and the residue, dissolved in muriatic acid, again evaporated and dissolved in water; or the metallic ingredients of the nitric acid solution may be precipitated by potassa, and the precipitate dissolved in muriatic acid. Into either of these solutions, the plate of iron is immersed. Zinc is sometimes employed to precipitate copper, but as this separates iron also if present, it is liable to fallacy. Even if the solution do not contain iron, yet if there be an excess of acid, and the zinc itself contain that metal, it will first be dissolved by the acid, and then precipitated by the zinc; for this reason its use is improper. Occasionally the precipitated copper, before it is weighed, is mixed with oil and borax, and subjected to heat in a crucible, by which it is freed from impurities, and the metal is thus obtained in its pure state.

Assay of Copper Alloys. Perhaps there is no metal, the alloys of which are more numerous and more useful than those of copper. It is of consequence, therefore, to be able by analysis to ascertain the proportions of the ingredients which they contain. It must be remarked, however, that though, by the aid of chemistry, we can ascertain with precision, not only the ingredients, but the proportions of the substances contained in these alloys, yet we often fail in forming an alloy possessed of all the properties of that subjected to analysis. This depends, in a great measuse, on the difference in the purity of the metals which we employ; a slight difference in these causing an alteration in the properties of the alloys which they form. The assay of these ores is also useful, as it enables us to procure from them the metals in their separate state. This is chiefly practised with the view of obtaining the copper.

The most important of the alloys of copper are those with tin. Tin, when added to copper, renders it harder, more sonorous, and more fusible: hence it is employed in the formation of bell-metal, and the other useful alloys of copper. When copper is alloyed with tin in the proportion of 100 of the former to about 8 or 12 of the latter, it forms the metal employed in the manufacture of ordnance. Bronze, and bell-metal, are composed of about 100 copper and from 10 to 20 of tin, to which occasionally a little zinc, and sometimes also antimony is added.

When the tin is in larger proportion, as about 30 of copper to about 15 of tin, the alloy is speculum metal, which is very hard, and admits of a fine polish. With this, a little zinc, silver, and arsenic, are mixed.

When the alloy consists only of copper and tin, we have an easy way of separating these metals. Tin not only is more easily oxidated by heat and air than copper, but the protoxide of the former metal has the property of depriving the protoxide of the latter of its oxygen, by which it is reduced. We have only therefore to subject the alloy to heat to obtain the copper in its metallic form. In this process we do not procure the whole of the copper existing in the alloy; besides, if we apply the heat by which the metals are oxidated too long, the tin attracts more oxygen from the air, and does not thus deprive the protoxide of copper of its oxygen. Thus Fourcroy found, that when he exposed an alloy of 80 of copper and 20 of tin to heat and air, till they amounted to 104, 54 parts of copper were obtained by afterwards subjecting the whole in a covered vessel to a high temperature. When, however, 100 parts of the same alloy were heated with access of air till they increased to 117, a very minute quantity of copper was obtained from them by the subsequent heating. According to Fourcroy, when copper is to be obtained by the method just mentioned, the alloy, supposing it composed of 80 copper and 20 tin, should be heated in the air till it gain about 6 or 7 parts in weight, and then subjected to a high temperature in close vessels. When the alloy has been too much oxidated, it must be mixed with the due proportion of alloy, and then exposed to a high temperature, by which a large quantity of metallic copper will be procured.

Occasionally a little nitre, or black oxide of manganese, is mixed with the alloy, by which the oxidation is more speedily accomplished. Some glass or salt should also be added, to increase the fusibility of the oxide of tin formed, and thus allow the metallic copper to fall to the bottom. The most accurate experiments on this subject on a large scale, are those of Pelletier and Darcet, which were done by exposing the alloy to heat and air, and by the addition of black oxide of manganese.

In one of these, 400 lb. of alloy, known to be composed of 80 copper and 40 tin, were heated, and constantly stirred till they increased to 425 lb. 2 oz. These were added to 800 lb. of alloy brought to a state of fusion in a reverberatory furnace, and the mixture constantly stirred during 20 minutes, and occasionally afterwards for 9 hours. The fused metal was then drawn off, and amounted to 761 lb. 12 oz.; 7 lb. 4 oz. of metal were also obtained during the trials to ascertain its purity, and the scoria yielded 64 lb. more, making in all 833 lb.; that is, very nearly 70 parts of copper from the 100 of alloy, which contained 80 of this metal.

In another experiment, 800 lb. of alloy were melted in the furnace, and 25 lb. of oxide of manganese were added to them. The mixture was then well stirred, and in two hours afterwards 15 lb. more of manganese were thrown in, a similar quantity being added every two hours till the whole amounted to 100 lb. and the fusion and occasional stirring were continued during ten hours. At the expiry of this time, the copper was drawn off, and amounted to 520 lb. that is, 65 per cent. of the alloy employed. The scoria still retained a good deal of copper, but this was not extracted from it.

When the alloy contains silver, it may be assayed by dissolving it in nitric acid, precipitating the silver by muriate of soda, and the copper by a plate of iron.

Tin.

Different methods are followed in reducing the ores of tin.

The ore which is procured from the mines of Cornwall, after being *hand-dressed*, is freed from impurities by stamping, as has been described under gold, after which, it is roasted in a reverberatory, to drive off the sulphur, part of which, however, is acidified, and unites with the copper and iron of the ore. The ore is again washed, by which it is nearly freed from all impurities; it is then mixed with one-fifth of its bulk of culm, and subjected to heat in a reverberatory for about six hours, during which the oxide of tin is reduced, and the metal collects at the bottom, covered with a black scoria. The tin is then drawn off into a shallow pit, in which it is freed from the scoria which collects on its surface. It is then taken out with ladles, and poured into moulds.

The metal thus obtained is afterwards exposed to a gentle heat in a small reverberatory furnace, by which the purest part of it melts first, and is drawn off. This forms grain tin; what is left behind is common tin, which contains a small portion of iron, copper, and arsenic.

The water employed in the second washing of the ore contains a considerable quantity of sulphate of copper, on which account it is kept and decomposed by iron. The scoria separated from the tin, when drawn from the reverberatory, retains a good deal of the metal—it is therefore stamped and melted along with the ore.

The stream tin stone of Cornwall is melted in a different way. As the ore is in a powdery state when procured, it is submitted to a stream of water, by which a great deal of the impurities are removed. It is afterwards bruised, and passed through wire sieves.

It is then thrown, with alternate quantities of charcoal, into a blast furnace, in which it is reduced, and escapes through a channel at the bottom into pits; the scoria being removed as it collects, and thrown again into the furnace.

The metal is then put into a large iron pot, in which it is kept fused. When in this state, pieces of charcoal are plunged into it, which cause a fresh quantity of scoria to be separated. The metal is then *tried* by removing a quantity in a ladle, and pouring it into the pot. If it appear bright like silver, and of uniform consistence, it is pure. After this it is poured into moulds, and forms good grain tin.

Assay.—In assaying an ore of tin, it is first reduced to coarse powder, and then washed, to free it from earthy matter. If it contain arsenic, which is known by its emitting the odour of garlic when fused before the blow-pipe, it must be exposed to heat with charcoal, till the vapours of arsenic cease to be emitted. What remains is then mixed with pitch and saw-dust, subjected to a strong heat in a crucible, lined with charcoal. The metallic button collected at the bottom is tin.

Lead.

The only ore of lead from which the metal is extracted is galena, the smelting of which is very simple.

The ore after being brought from the mine is *hand-dressed*, by which it is freed as much as possible of impurities. What remains is then washed, to remove still farther any extraneous matter, and is put into a reverberatory furnace, where it is speedily made red hot. When in this state it is frequently stirred, and when it begins to become soft, the heat is reduced till the whole of the sulphur is expelled. The fire is then made brisk, by which the lead is melted, and collects at the bottom. A little lime is then thrown in to thicken the scoria, and the lead is drawn off into oblong moulds; a sufficient heat is again applied to the scoria, by which another portion of lead is procured. The lead obtained in the first operation is considered the best, as it is more malleable than the other.

Assay.—The assay of galena is very simple. It may be done either in the dry or the humid way.

The lead ore is first reduced to powder, and then digested in diluted nitric acid. To the solution, after filtration, sulphate of soda is added, which throws down the sulphate of lead: 100 gr $=$71 lead.

Or, the ore is first roasted, and then fused with thrice its weight of black flux, and covered with salt. The metallic button at the bottom of the vessel is the lead, containing the other metals present in the ore, which however are in very small quantity.

Should the ore contain silver, the metallic button thus obtained must be subjected to cupellation, or it may be dissolved in nitric acid, and muriate of soda added to the solution. The precipitate must then be digested in weak nitric acid, which will dissolve the muriate of lead, and leave the silver; 100 of the precipitate after this, when dried, $=$75.3 of silver.

Arsenic.

Arsenic very frequently exists with other metals. It is not, however, used in the metallic state in the arts. The compound of it generally employed is the white oxide, or, as it is commonly called, white arsenic, which is frequently obtained in the processes for extracting other metals from their ores.

White arsenic is obtained by subjecting the arsenic ores to heat, in large cast iron boxes, to which flues are closely luted. These are heated by flues from a furnace. When red hot, about 15 lb. of the ore are thrown in, and when the whole of the volatile matter has sublimed, another portion of ore is put in, and the process is continued for about 12 hours, during which time about 150 lb of the ore have been employed. What is collected in the flues of the boxes is broken off by hammers, and is freed from any foreign matter adhering to it.

Another preparation of arsenic much used in the arts, is yellow orpiment, which is procured in the same way; the ore being previously mixed with half its weight of sulphur.

Metallic arsenic is easily obtained from the white oxide, by heating it with carbonaceous matter; the sublimed metal being condensed in cool receivers.

Assay of Arsenic Ore.—The most accurate method of assaying an ore of arsenic, is that pointed out by Chenevix, which consists in acidifying the arsenic, and precipitating it by a salt of lead. For this purpose the ore is treated with nitric acid, so as completely to acidify the arsenic. Potassa is then added, and afterwards nitrate of lead, which throws down a precipitate, which, after exposure to a low red heat, must be weighed. If it is entirely soluble in nitric acid, 100 of it=22 of metallic arsenic.

If any of the precipitate is not soluble in nitric acid, it is sulphate of lead, the acid of which is formed by the action of the nitric acid on the sulphur of the ore. The weight of what is left, after the action of the nitric acid, will indicate that of the precipitate dissolved.

A more easy way of assaying the ore, though not quite so accurate, but sufficiently so for the purposes of art, is, to dissolve the ore slowly in muriatic acid, to which a little nitric acid is added. In this way the metal is dissolved, and the sulphur is left. The quantity of this indicates that of the arsenic; 100 being equivalent to about 138 of metal.

Cobalt.

Cobalt is not procured in its metallic state for the purposes of art. The preparation of it in general use is the oxide. Two different kinds of this are employed, zaffre and smalt; the former of which is the oxide mixed with a quantity of vitrifiable earth; the latter is the oxide which is brought to the state of glass by being exposed to heat with some fusible substance. These are prepared in Saxony, in Bohemia, Silesia, and Lorrain. That from the former is considered the best. To prepare zaffre, the cobalt ore is exposed to heat by means of the flame of wood, which is made to play on it. The vapour arising from the ore is conveyed through a long flue, in which it is condensed. After the vapours have ceased to arise, the ore is removed and reduced to powder, and a second time exposed to heat. It is again reduced to fine powder, and passed through sieves; and after this is mixed with powdered flints moistened. In this state it forms zaffre. Smalt is prepared by mixing the oxide of cobalt, obtained in the above process, with about equal parts of potashes and powdered flints. The mixture is exposed to heat in large pots, and frequently stirred, when in the fused state, during 10 or 12 hours. It is then taken out in ladles, and dropped into cold water, by which it is afterwards more easily reduced to powder.

The powdering of smalt is performed by large stone rollers, inclosed in cases of wood. When reduced to powder, it is of a fine blue colour, and is sometimes called azure blue. It is employed not only in the arts, to impart its colour to substances with which it is fused, but likewise in washing, to prevent linen from becoming yellow.

Cobalt is obtained in the metallic state by deflagrating 4 parts of smalt, 2 of nitre, and $\frac{1}{2}$ of charcoal. The residue of the deflagration must be again subjected to a similar process, and afterwards fused with 2 parts of black flux. The product of this operation, weighing about one-fifth of the smalt, is mixed with one-sixth of its weight of nitre, and the same quantity of black oxide of manganese, and exposed to a strong heat in a covered crucible for about an hour. By this process it is freed from iron; it still, however, retains a small quantity of arsenic; or the product of the deflagration may be dissolved in nitric acid, and carbonate of potassa added to the solution, as long as a brownish precipitate is thrown down; when, however, the precipitate falls of a violet colour, the addition of the salt must be discontinued. By this means we get quit of the iron, and leave the cobalt in union with nitric acid. The nitrate is then exposed to heat, the acid is expelled, and the oxide may be reduced by fusion with black flux. By these processes cobalt is obtained sufficiently pure for many purposes.

Assay.—The assay of cobalt ore may be performed, though not with great accuracy, in the dry way. The ore is mixed with saw-dust, and roasted to expel the arsenic, and the residue afterwards exposed to an intense heat for about 15 minutes, with its own weight of a mixture of carbonate of potassa and tartar. The metallic button collected below is cobalt. The scoria of this operation contains a considerable quantity of metal; the whole of the cobalt is therefore not procured, and it is even doubtful if by this means the whole of the arsenic is expelled.

Mercury.

Different methods are practised for procuring mercury from its ores; they are however all very simple.

In Spain the cinnabar is collected and divided into three portions.

1st, The richest part of the ore.

2d, That which contains less metal.

3d, The powder of the two first.

These are exposed to heat in a furnace, by which the mercury is expelled. The furnace employed in this operation is of a particular construction. It consists of a long horizontal building, divided into an under and an upper compartment, by a grating of iron. On this are placed flat rough stones, over which ore No. 2. is first put, and then ore No. 1. A layer of ore No. 2. is placed above this; and on the top of the whole is laid ore No. 3. made into a sort of bricks, with clay kneaded and dried. Wood is then kindled in the lower compartment of the furnace, by which the moisture is driven off. The fire is then continued till the sulphur begins to burn; after which the heat excited by the combustion of the sulphur is sufficient to volatilize the mercury, which is condensed in the receiver attached to the furnace. Along with the mercury there is collected a quantity of sooty matter, which is removed by placing the metal on an inclined table.

In this process there is a considerable loss of mercury, as the sooty matter which is thrown away retains a great deal of the metal.

In Germany, the finer part of the ore is separated from the coarser part, and is reduced to powder. It is then mixed with about one-fifth of slaked lime, and put into iron retorts, each of which holds about one-half cwt. From 40 to 50 of these are built into a furnace, and have receivers adapted to them. Heat is applied to the retorts, by which watery vapour is at first expelled. The receivers are then luted by means of clay, and the mercury which comes over is condensed in them. By this process 100 lbs. of ore yield from 6 to 10 oz. of mercury.

Assay.—The assay of the ore of mercury is very simple. Cinnabar, the ore usually employed for yielding the metal, is reduced to powder, and digested in nitro-muriatic acid, composed of one of nitric and three of muriatic acid, diluted with water, till the whole of the soluble matter is extracted. Carbonate of potassa is then added to the solution, and the precipitate, after being dried, is mixed with lamp-black, and exposed to heat in a retort, to which a receiver is adapted. By this means the mercury is expelled in the metallic state.

The ores of mercury which contain silver are assayed in the same way, so as to ascertain the quantity of mercury. The insoluble residue is then roasted, to drive off the sulphur, after which it is mixed with twice its weight of pearl-ashes, and again exposed to heat in a crucible. The product is then digested in muriatic acid, which dissolves the alkali, and leaves the silver in its metallic state.

A more easy way of assaying the mercurial ores is to reduce them to powder, and to mix them with one-fourth part of lime, and as much iron filings, and then expose them to heat in an iron or earthenware retort, by which the mercury is expelled, and is collected in a receiver.

Manganese.

Manganese is not used in the arts in its metallic state. The black oxide, which is a native production, answers, without any preparation, all the purposes for which the metal is employed.

Zinc.

The ores of zinc used in metallurgy, are calamine and blende. From these the metal is procured by a very simple process. The ore, after being hand-dressed, to free it from foreign matter, is roasted, by which the sulphur of the former and the acid of the latter are expelled. The product is then washed, by which the lighter matter is separated, and the heavy part which remains is mixed with one-eighth of its weight of charcoal. The mixture is next reduced to powder in a mill, in which state it is put into the pots to be smelted. The pots in which the smelting is performed resemble oil jars in shape. Through the bottom of each there passes a tube, the upper end of which terminates by an open mouth near the top of the pot, the lower end goes through the floor of the furnace into water. The pots are filled to the upper end of the tube with the mixture of ore and charcoal, and an intense heat is applied to them, by means of a furnace. As the ore is reduced, the zinc is volatilized, and escapes through the tube into the water, where it is condensed in the form of globules. These are afterwards melted and cast into moulds.

Zinc, as thus procured, is not pure; it almost always contains iron, manganese, arsenic, and copper.

To free it from these, it is again melted, and then well stirred along with sulphur and fat, the former of which combines with the foreign metals, and leaves the zinc nearly pure, while the latter prevents this metal from being oxidated.

Assay.—The assay of zinc ores may be performed in two different ways.

The simplest is, reducing the ore by charcoal. For this purpose, after being freed from impurities, it is roasted, to drive off the sulphur. It is then mixed with one-half its weight of charcoal in powder, and exposed to a strong heat, for about an hour, in an earthen retort, the mouth of which terminates in water. The zinc condensed in the water and in the neck of the retort is collected and weighed.

The second method of assay is, to expose to a strong heat for about an hour the mixture of ore and charcoal, in a covered crucible, with slips of copper, by which means the two metals unite. After the process is finished, the product is washed, and the weight which the copper has acquired indicates the quantity of zinc in the ore.

Bismuth.

Bismuth occurs native and mineralized by oxygen and sulphur, and is very easily obtained from its ores.

When native bismuth, and the oxide, are employed to yield the metal, they are merely exposed to heat, in contact with fuel, generally in shallow pits dug in the earth. The metallic matter which collects at the bottom is then mixed with an equal weight of black flux, and put into a crucible, and covered with common salt, to about the depth of half an inch. A strong heat is applied for a short time, by which the mixture fuses, and the bismuth collects at the bottom of the pot.

Instead of the above process, the ore is sometimes mixed with half its weight of borax and of pounded glass, and subjected to heat in a crucible lined with charcoal.

When the sulphuret of the metal is employed, it is first roasted by a gentle heat, to drive off as much of the sulphur as possible. After this, it is mixed with black flux, and subjected to heat, covered with common salt, as in the first process.

Bismuth obtained by these different processes contains in general lead, silver, or cobalt, provided these were present in the ore; it is sufficiently pure, however, for most purposes.

Assay.

The assay of the ores of bismuth, with the view of ascertaining the quantity of that metal, is performed by means of nitric acid. The ore is dissolved in this acid, diluted with one-half its weight of water, by the aid of heat. To the solution, a large quantity of water is added, by which oxide of bismuth is precipitated. The fluid after filtration is then evaporated as far as possible, without causing the deposition of any of its ingredients. Muriatic acid is then added, and the precipitate is digested in nitric acid. With the solution thus obtained, a large quantity of water is mixed, and the whole of the oxide of bismuth is thrown down. This, with the former precipitate, is then fused with black flux, by which the bismuth is procured in the metallic state.

If the ore contain silver, the precipitate thrown down by muriatic acid will become black on exposure to light.

To ascertain the quantity of this metal present in the ore, the residue of the precipitate, after the digestion in nitric acid, must be washed, and then exposed to a red heat, 100 gr. of it = 75.3 of silver.

Or, the metallic button, obtained by the fusion of the ore with black flux, may be subjected to cupellation, by which the base metals will be oxidated, and absorbed by the dish, and the silver will be left.

Antimony.

The sulphuret of antimony is the only ore of this metal that is used in commerce. This is purified merely by fusion, in which state it is usually employed in the arts. For purifying the sulphuret, two methods are employed.

1*st*, The ore, after being broken, and freed as much as possible from stony matter, is put into a large crucible, in the bottom of which there is a small hole. From this there proceeds a tube, which passes through the furnace in which the crucible is placed, and terminates in a reservoir. As the heat is applied, the sulphuret fuses, and runs through the tube into the reservoir, while the stony matter is left in the crucible.

2*d*, The fragments of the sulphuret, after being freed from the earthy ingredients, are put on the hearth of a reverberatory furnace, and covered with charcoal. They are then brought to the fluid state, while the foreign ingredients float on the surface, and are removed by ladles. When fluid, the sulphuret is poured into moulds, in which state it forms common, or crude antimony.

From the crude antimony the metal is procured by different processes. The first of these is, by what is called *scorification.* For this purpose 8 parts of finely powdered sulphuret are mixed with 6 of crude tartar and 3 of nitre, and the mixture is thrown in successive portions into a red-hot pot. When the vessel is nearly filled, it is covered, and a strong heat is applied to it for about half an hour; the fused matter is then either allowed to cool, or it is poured into a conical iron vessel, greased in the inside, in which it separates into different layers; the upper consisting of scoriæ of alkaline matter and oxide of antimony; the lower one of antimony in its metallic state.

It has been recommended by some to deflagrate the nitre and tartar, previous to the sulphuret being mixed with them; as, however, the use of the nitre is to acidify the sulphur, it is best to mix the whole of the substances together, and then to deflagrate them. In this process it is necessary to avoid using an excess of tartar and nitre, otherwise not only the expense is increased, but less metal is obtained. The proportions above stated are what Lemery found to answer best.

The second method of reducing the sulphuret is by *roasting* The ore, reduced to small pieces, is placed on the hearth of a reverberatory furnace, and heat is applied to it, by which the sulphur is consumed, and the antimony is oxidated. In this part of the process it is necessary that the heat be at first slight, otherwise the sulphuret runs into cakes. As the sulphur is consumed, and the fusibility diminishes, the residue is brought to a red heat. When it ceases to emit the odour of sulphurous acid, the roasting is stopped, and the oxide is removed. In this state it still contains a small quantity of sulphuret.

Different methods are followed for procuring the metal from the oxide. It is sometimes mixed with one half its weight of crude tartar, and exposed to a strong heat, in covered vessels, by which the oxygen of the oxide unites with the carbon of the acid of the tartar; and the metal, in a state of fusion, falls to the bottom of the vessel. There is also formed a compound of the antimony with the sulphuret of potassa, which is generated by the union of the alkali of the tartar with the sulphur contained in the oxide. The quantity of metal obtained by this process amounts to about 70 per cent. of the oxide employed, and 100 of the sulphuret yield about 70 of oxide.

Another method of procuring antimony, is by melting the oxide along with fat and charcoal. When the mixture is in a state of fusion, nitre, in the proportion of about 1 oz. to the pound, is gradually added. The whole is then poured out, and allowed to cool. By this means more of the metal is procured than by the above process.

The third method of obtaining antimony, is by adding some body as a metal, which unites with the sulphur. For this purpose iron is always employed. In decomposing the sulphuret in this way, 8 parts of iron, in small pieces, are heated to whiteness in a crucible; 16 parts of coarsely powdered sulphuret are then added, and the vessel is covered for a short time. When the whole is in fusion, 3 parts of nitre are gradually thrown in, and the product, after a short time, is poured into greased cones, which must be gently struck from time to time, as the matter consolidates, to cause the metal to fall to the bottom. When the whole has become solid, about 10 parts of antimony are found in the vessel, which, however, still retains iron and sulphur. To free it from these, it must be again melted with 3 parts of nitre, and 2 of sulphuret, which must be repeated twice before the antimony is obtained pure. From 18 of sulphuret 8 of metal are procured by this process.

Assay of the Sulphuret.

Sulphuret of antimony, besides sulphur and antimony, contains also lead, iron, copper, stony matter, and occasionally silver. The assay, with the view of ascertaining the quantity of antimony, is, however, easily performed, by digesting the sulphuret in nitric acid. After the action has ceased, the solution is poured off, and the insoluble residue is dissolved in nitro-muriatic acid. To the solution, a large quantity of water is added, and the precipitate thrown down, is mixed with twice its weight of crude tartar and a little nitre, and exposed to heat, by which the antimony is obtained in the metallic state

METALS. The metals, if we except the bases of the alkalies, and earths, are distinguished by hardness and tenacity, great specific gravity, opacity. and peculiar brilliancy, generally termed metallic lustre.

The properties of the metals have been already described in the article Chemistry. At the time when that article was written, they amounted to 27.

1 Iron.	Arsenic.
Copper.	Manganese.
Lead.	10 Gold.
Zinc.	Silver.
5 Tin.	Platinum.
Mercury.	Iridium.
Antimony.	Osmium.

15 Rhodium.	Chromium.
Palladium.	Titanium.
Bismuth.	Tungsten.
Cobalt.	25 Tantalum.
Nickel.	Cerium.
20 Molybdena.	27 Uranium.
Tellurium.	

Since then, three new metals have been discovered, and an account has been given of a fourth, of the existence of which, however, considerable doubts are entertained.

The three first are Selenium,
Cadmium,
Wodanium.
The other is Vestium, or Sirium.

Selenium.

The sulphur procured from the pyrites of Fahlun, when employed in the preparation of sulphuric acid, was observed by Bjuggren to leave a reddish brown substance, which, by some chemists, was supposed to contain arsenic; on which account the use of the pyrites of Fahlun was discontinued. Berzelius has subjected this brown matter to analysis, and has discovered, that besides iron, copper, lead, zinc, tin, mercury, and arsenic, it contains a peculiar substance, possessed of metallic properties, to which he has given the name of selenium, (from selenė the moon,) to recal its analogy with tellurium, which it very much resembles.

Berzelius, in his analysis of the brown matter left after the preparation of sulphuric acid, digested it in nitro-muriatic acid Water and sulphuric acid were then added; and the mixture was filtered, by which sulphur and sulphate of lead were separated. To a portion of the filtered fluid ammonia was added, which threw down a precipitate, which, when heated with potassium, was decomposed with ignition. This precipitate was partly soluble in water; the solution acquired a brown colour; and, on the addition of nitric acid, deposited a reddish substance, which, when brought in contact with flame, communicated to it a blue tinge, and emitted the odour of horse raddish. This made Berzelius suppose that it contained tellurium; but he afterwards found that it was caused by the new metal When the fluid which had yielded the precipitate on the addition of ammonia was subjected to distillation, a yellowish liquid was collected, which contained sulphurous acid, and deposited a brown powder. A black substance was sublimed into the neck of the retort. The fluid, when boiled, deposited more of the brown powder; and the sublimate, when washed, afforded the same matter. These were selenium.

To procure selenium free from the other substances contained in the pyrites, Berzelius passed sulphuretted hydrogen through the fluid obtained by filtration, after the digestion of the substance in nitro-muriatic acid

a By this means, an orange-coloured precipitate was produced, which was treated with nitro-muriatic acid.

b Water was added to the solution, which occasioned a copious white precipitate.

c This, when heated to redness, yielded a chrystalline sublimate, having a strong acid taste; and when subjected to heat with soda and borax, it left a metallic button, possessing the properties of tin. It was therefore an oxid of tin, in union with the sublimed acid, which Berzelius found was an acid of selenium

d To the liquid from which the above precipitate was obtained, muriate of baryta was added, which threw down the sulphuric acid. The fluid, after filtration, being subjected to heat, afforded a white chrystalline sublimate, and a whitish matter was left behind.

e The sublimate (*d*) was an acid having a metallic taste, communicated to it by mercury; for when precipitated by potassa, it yielded mercury on the application of heat. What remained was potassa in union with the acid.

f This, when mixed with muriate of ammonia, and distilled, first yielded water and ammonia. Selenium then sublimed in small quantity. The residue, when washed, left a coarse brown powder. which was selenium, and which was sublimed to free it from impurities.

g The substance left after the distillation (*d*) was found to consist of baryta, copper, and tin, in union with the acid of selenium, and of arseniate of baryta.

Selenium is of different colours, according to the mode in which it is prepared. After being fused, it has a deep brown colour, and metallic lustre. When allowed to cool slowly, its surface becomes rough. In the former case, the fracture is conchoidal, and presents the appearance of lead; in the latter, it is granular, and resembles a piece of cobalt.

When, on the contrary, selenium is precipitated from some of its combinations, it assumes a cinnabar-red colour; and in some particular cases, the colour approaches that of gold. When selenium is in powder, it is red; but when pounded, it sticks together, and becomes grey.

The specific gravity of selenium is 4.32. It is a bad conductor of caloric; a small piece of it, which is heated to near the fusing point at one end, may be held by the other end in the hand. It is a very imperfect conductor of electricity; and, what is remarkable, it has not been made electric by friction.

When selenium is heated to 212°, it becomes semi-liquid, and, at a few degrees higher, it fuses. As it cools, it becomes semifluid, and then passes into the solid form. When semifluid, it may be drawn into fine threads, or beat into plates, which when thin, are transparent. These, when viewed by transmitted light, are red, by reflected light they are grey. Selenium may be made to assume the chrystalline state, though with difficulty. When slowly deposited from a solution of some of its salts. it puts on the dendritic form, the chrystals of which appear, by the aid of a glass, to be prisms terminated by pyramids.

When selenium is heated in close vessels, it boils, and passes off in vapour, of a colour rather darker than that of chlorine, and which condenses in the cool part of the apparatus in black drops.

When heated in the air, or in very large vessels, a red-coloured vapour is formed, which condenses in powder. When the metal is heated in contact with flame, the flame acquires at its edges a blue colour, and the selenium is volatilized, with the odour of horse-raddish. The products in this case are selenic acid, and a compound of selenium and oxygen, similar to carbonic oxide. Berzelius has therefore called it selenic oxide.

Selenic oxide is procured by washing repeatedly the product formed in the above experiment. It may likewise be obtained by heating selenium in a large vessel containing oxygen, or by dissolving the compound of the metal and sulphur in nitro-muriatic acid. It is sparingly soluble in water, but communicates to that fluid its peculiar odour. It does not seem to unite with the alkalies.

Selenic Acid. Selenium combines with a larger proportion of oxygen, and forms a compound possessed of acid properties. When a stream of oxygen is passed over selenium in a state of fusion, the metal takes fire, and burns with a white flame, having a greenish tinge at the edges; the product is selenic acid, which condenses in the cool part of the apparatus. Selenic acid is more easily procured by dissolving selenium in nitro-muriatic acid. By evaporating the solution, the undecomposed acids pass off, and selenic acid is left in the form of a white mass. When this is subjected to a higher temperature it volatilizes without becoming fluid. The temperature at which it passes into vapour seems to be below that of boiling sulphuric acid. The vapour has exactly the appearance of chlorine, and condenses in the cool part of the apparatus, in long four-sided needles.

Selenic acid has a sour taste, leaving a burning sensation on the tongue. It is very soluble in cold water, and in almost any quantity of that fluid at a boiling heat. The solution on evaporation deposits acicular crystals, but by cooling slowly a saturated warm solution, the acid assumes a prismatic figure.

Selenic acid forms saline compounds with the alkalies, earths, and metallic oxides. It is soluble in alcohol, and yields, on distillation with this fluid, a liquid having an etherial odour; at the same time a portion of selenium is formed, and part of the acid remains behind.

Berzelius endeavoured to ascertain the composition of this acid, by passing chlorine over the metal. In this experiment, 1 of selenium united with 1.79 of chlorine. According to Berzelius, 1.79 of chlorine are equivalent to 4.043 of oxygen—100 of selenium, therefore, unite with 40.43 of oxygen, to form selenic acid.

In another experiment, the product formed by passing the gas over selenium was dissolved in water, and the muriatic and selenic acids generated, were precipitated by nitrate of silver. The precipitate, after the seleniate was removed by boiling diluted nitric acid, weighed 7.2285 = 1 38 of muriatic acid = 40.274 of oxygen. According to this experiment, 100 of selenium combine with 40.274 oxygen.

Berzelius is inclined to consider, that the true composition of the acid is

100 selenium, 71.26,
40 33 oxygen, 28.74;

and that it contains 1 atom of selenium, and 2 of oxygen. If so, the number for selenium is 4.959, that of oxygen being 1.

Dr. Thomson, from calculation founded on the former of these experiments, infers that the acid is composed of

100 selenium,
38 oxygen.

The cause of this difference is owing to a difference entertained with respect to the constitution of the precipitate, afforded by the nitrate of silver. According to Dr. Thomson, the equivalent number for selenium is 5.125, that for the acid 7.125.

Chloride of Selenium.—When selenium is kept in chlorine, the gas is absorbed, the metal becomes hot, and a brown-coloured liquid is formed, which assumes a white colour as the absorption of the gas proceeds. According to Berzelius, the product of this experiment is selenic and muriatic acids. According to Sir H. Davy's doctrine, it is a chloride. When dissolved in water, it forms a transparent colourless acid solution.

When this compound is heated in contact with selenium, a yellowish fluid is formed, which, when put into water, decomposes it, and generates muriatic and selenic acids, and deposits selenium. It is probable that this is another compound of selenium and chlorine, containing less chlorine. If so, it is the protochloride, and the former is the perchloride of the metal.

Seleniuretted Hydrogen.—Selenium combines with hydrogen, and forms a gaseous fluid, called seleniuretted hydrogen, which is procured by adding muriatic acid to the compound called seleniuret of potassa. It is absorbed by water, forming a transparent colourless solution, having a hepatic taste, and which stains the skin red, and reddens litmus. The solution, after being kept for some time, becomes turbid, from the deposition of selenium. When exposed to the air, the seleniuretted hydrogen is decomposed. The same takes place when the gas is brought in contact with a moist body, and what is remarkable, the selenium penetrates the substance, if porous, and communicates to it a red colour.

Nitric acid causes no change on the solution of seleniuretted hydrogen in water.

The solution, when added to the metallic salts, throws down precipitates from them, which are in general black or brown. Those from a salt of zinc, manganese, and cerium, are however of a red colour. The former are considered seleniurets, the latter hydroseleniurets, and according to Berzelius, when exposed to the air, are converted into seleniurets of the oxide of the metals.

Seleniuretted hydrogen produces remarkable effects on the organs of respiration. When admitted into the nostrils, it excites a painful sensation, and destroys completely for several hours the sense of smell, followed by severe catarrh, deep pain of the chest, and expectoration of mucus, having the taste of the vapour of corrosive sublimate.

These effects are produced by a very minute quantity of the gas. Berzelius supposes that the seleniuretted hydrogen is decomposed by the moisture, and that the selenium adheres to the membrane of the nostrils and trachea. The eyes are likewise affected with inflammation when exposed to this gas.

Seleniuretted hydrogen, according to the experiments of Berzelius, is composed of

97.4 selenium,
2.6 hydrogen.

This compound of selenium may be considered analogous to sulphuretted hydrogen.

No compound of selenium and carbon has yet been formed, though from some experiments, it is conjectured that these bodies do unite.

Phosphuret of Selenium is formed, when selenium and phosphorus are heated together. The compound is fusible, and is of a dark colour, having a vitreous fracture. When digested in water, it decomposes this fluid; seleniuretted hydrogen is formed, and selenium is deposited.

Sulphuret of selenium may be procured by passing a stream of sulphuretted hydrogen through a solution of selenic acid, and then adding a few drops of muriatic acid, by which the sulphuret of selenium is precipitated of an orange colour. This compound is very fusible, passing into the liquid state at a temperature a little below that of boiling water. By the application of a stronger heat it volatilizes, and again condenses of an orange colour. Sulphuret of selenium, when heated in the air, burns, and emits the odour of sulphurous acid and of horse-raddish. When exposed to heat with selenic acid, it is decomposed, and the sulphur combines with the oxygen.

This compound is not easily acted on by nitric acid; nitro-muriatic acid, however, dissolves it.

Sulphuret of selenium is composed of

100 selenium,
60.75 sulphur.

Selenium, and the alkalies and earths.—By the action of selenium on the alkalies and earths, compounds are formed, analogous to those generated by the action of sulphur on these bodies. It is probable, therefore, that they are compounds of the bases with seleniuretted hydrogen, having the selenium in excess. If so, they are seleniuretted hydro-seleniurets.

When aqua potassæ is boiled on selenium, a solution is formed, having the colour and odour of sulphuretted hydro-sulphuret of potassa. The same compound may be obtained by exposing to heat selenium and potassa, or its sub-carbonate.

When an acid is added to the solution of this substance, selenium is precipitated.

Ammonia does not, either in the state of gas, or in solution in water, act on selenium.

When seleniuretted hydro-seleniuret of lime and muriate of ammonia are subjected to heat a reddish-coloured fluid distils over, which, when exposed to the air, emits ammonia, and deposits selenium. By the addition of a large quantity of water to it, selenium is also precipitated. There is left in the retort after the distillation, muriate, seleniate, and hydro-seleniate of lime. When selenium and lime are exposed to heat the two unite, and form a black substance destitute of taste and smell, and insoluble in water. On the addition of an acid to this, the selenium is left in the form of a spongy mass. This compound may be got crystallized, by exposing to the air a solution of hydro seleniuret of lime. The crystals appear to be four-sided prisms, with truncated summits.

The compounds formed with baryta, strontia, magnesia, and alumina, are insoluble. By the addition of an acid to them the selenium is separated, and the two last yield that metal on the application of heat.

Selenium and the metals.—Selenium combines with the metals, presenting with most of them the same phenomena as sulphur.

The seleniurets have in general a metallic aspect, and are usually more fusible than the metals which they contain. By the application of heat to them, the selenium burns with a blue flame, emitting the odour of horse-raddish.

Seleniuret of potassium.—When selenium and potassium are heated together, they combine, and during their union emit caloric, sufficient to raise the temperature of the compound to ignition, by which a portion of selenium is sublimed.

Seleniuret of potassium resembles iron in appearance, having a crystalline structure. When thrown into water, decomposition ensues, and hydro-seleniuret of potassa is formed. The solution is of a reddish colour, and possesses the property of keeping dissolved an excess of selenium, for, when nitric acid is added to it, selenium is deposited.

When selenium is heated with an excess of potassium, an explosion occurs, and the product is scattered about by the potassium which is converted into vapour. The compound formed in this instance, when put into water, is dissolved, and hydrogen is disengaged.

Seleniuret of iron may be procured by passing the vapour of selenium over iron filings, at a high temperature; during the union, caloric is evolved. The compound has a dark-grey colour, and metallic aspect. It is hard and brittle, with a granular texture. When heated at the flame of a candle, part of the selenium is volatilized. Seleniuret of iron, when acted on by muriatic acid, affords seleniuretted hydrogen. In this case the first portion of gas disengaged is decomposed by the air in the apparatus, and selenium is deposited, which gives to the liquid a reddish colour. Along with seleniuretted hydrogen, another gaseous fluid is given out, which has a disagreeable odour, is inflammable, and is not dissolved by water, nor by the solutions of the alkalies. When passed through a solution of proto-nitrate of iron, a black precipitate is thrown down.

Selenium unites with a less proportion of iron, and forms a compound not soluble in muriatic acid, and which, by exposure to heat, parts with the excess of selenium.

Seleniuret of copper is formed by passing seleniuretted hydrogen through a solution of copper, by which a dark-grey substance is precipitated, which, on exposure to heat, loses half of its selenium. and proto-sulphate of copper is left behind. This compound may also be procured by heating selenium and copper-filings together.

Seleniuret of lead—Selenium and lead unite with an evolution of caloric. The seleniuret is of a grey colour, and porous. When heated before the blow-pipe on charcoal, part of the selenium is oxidized, and sub-seleniate of lead is formed, which is afterwards decomposed, and seleniuret of lead is regenerated.

Selenium unites with more lead, and forms a compound less fusible than the former.

Seleniuret of tin is of a grey colour, and possesses the metallic lustre in a high degree. When exposed to heat, the selenium is volatilized, and the tin is oxidated.

Seleniuret of zinc.—When selenium and zinc are heated together, the melted selenium covers the surface of the zinc, but does not combine with it. If the heat be increased much above the fusing point, the former is volatilized, and the latter remains covered with a yellow pellicle.

When zinc, at an elevated temperature, is introduced into the vapour of selenium, an explosion occurs, and the vessel is lined with a lemon-coloured powdery substance, which is seleniuret of zinc. This is soluble in nitric acid, with the disengagement of nitric oxide.

Seleniuret of mercury.—When selenium and mercury are heated together, a substance resembling tin is formed. If mercury be in excess, this is expelled, when the compound is subjected to heat; the seleniuret then sublimes without fusing, and condenses in the form of white leaves, having a metallic lustre. Seleniuret of mercury is not easily acted on by nitric acid. When this is boiled on it, proto-seleniate of mercury is formed, and the nitric acid contains selenic acid. If muriatic acid be poured on the seleniate, selenium is precipitated; the oxygen of the selenic acid passing to the mercury, by which the red oxide is generated. Seleniuret of mercury is soluble in nitro-muriatic acid.

Seleniuret of antimony has a metallic lustre and a crystalline appearance.

Seleniuret of arsenic.—When arsenic is put into fused selenium, the two metals unite, and a black mass is produced, which, when heated to redness, boils, and a sublimate is formed, which appears to be per-seleniuret of arsenic.

Seleniuret of platinum.—Platinum in powder, and selenium, readily combine with the extrication of caloric, and generate a grey substance, which, when subjected to heat, parts with the selenium, and leaves the platinum. On this account the seleniates act readily on a platinum crucible.

Seleniuret of palladium is of a grey colour, and before the blow-pipe emits part of the selenium.

Seleniuret of bismuth has a silvery colour and metallic lustre, and requires a red heat for its fusion.

Seleniuret of tellurium is fusible, and sublimes in the form of a metallic mass—it is also oxidated, and generates seleniate of tellurium.

Selenic Acid and Bases.

The affinity of selenic acid for the bases seems to be below that of arsenic acid. The neutral seleniates are either insoluble, or sparingly soluble in water. Berzelius asserts that the acid of them contains just as much oxygen as exists in the base. The quantity of oxygen in a base sufficient to saturate 100 of acid is 14.37.

Selenic acid forms two classes of super-salts; the first contains twice as much acid as exists in the neutral compounds, of course there is four times the quantity of oxygen that there is in the base. These salts Berzelius calls bi seleniates. The other super-salts appear to contain four times the acid of the neutral compound; they are therefore termed quadri-seleniates.

Selenic acid forms also sub-salts with the alkalies, and with some of the metals. The alkaline seleniates have a saline taste. Those, with the earths and the metals, possess in general the taste of the base.

The compounds of selenic acid are decomposed by heat, which seems to be occasioned by their containing foreign inflammable matter. The same occurs when the seleniate of an alkali or earth is heated with charcoal. Carbonic acid and carbonic oxide are formed, and a small quantity of selenium sublimes. When a metallic seleniate is treated in this way, the selenium unites with the metal of the base, and forms a seleniuret.

Seleniate of potassa is very soluble in water, and may be obtained in small metalline grains by the evaporation of the fluid. When evaporated to dryness, the residue attracts moisture on exposure to the air. When heated to redness it fuses, and becomes of a yellow colour, but again assumes its former appearance when it cools. It is insoluble in alcohol.

Bi-seleniate of potassa is deliquescent, and soluble in water, but crystallizes with difficulty. By the application of long continued heat, half of the acid is driven off. This salt is sparingly soluble in alcohol.

Quadri-seleniate of potassa cannot be obtained crystallized. It is very deliquescent.

Seleniate of soda has the taste of borax. It is very soluble in water, and affords, on evaporation, small crystalline grains, which do not deliquesce. It is not soluble in alcohol. By exposing this salt with muriate of ammonia to a red heat, muriate of soda is left. In this way 100 of seleniate afforded 66$\frac{2}{3}$ muriate of soda = to 35.5 soda. The salt is therefore composed of

64.5 acid.
35.5 soda.

Bi-seleniate of soda is obtained in the crystalline state. When heated, it undergoes fusion; and if the heat be strong, it parts with its excess of acid, and forms the seleniate. This salt is composed of 77.83 acid,
22.17 soda.

Quadri-seleniate of soda crystallizes in needles. It does not alter by exposure to the air.

Seleniate of ammonia is obtained in four-sided prisms, which are deliquescent.

Bi-seleniate of ammonia is obtained by exposing a solution of the preceding salt to the air; and the

Quadri-seleniate of ammonia is procured by adding selenic acid to a solution of the bi-seleniate, or by evaporating the solution by heat.

Seleniate of ammonia is decomposed by heat, water and ammonia are first disengaged; the selenic acid is then decomposed by the ammonia, and selenium is left in the retort.

Seleniate of lime is sparingly soluble; when heated in a glass vessel it forms bubbles in the glass, and at last perforates it.

Bi-seleniate is formed by dissolving the above salt in the acid.

Seleniate of baryta is insoluble in water. It is composed of 100 acid,
137.7 earth.

Bi-seleniate is formed by dissolving carbonate of baryta in selenic acid. It is soluble, and crystallizes. It is composed of 100 acid and about
68 baryta.

Seleniate of Strontia is insoluble.

The *bi-seleniate* is sparingly soluble in water. By the application of heat, the excess of acid is expelled.

Seleniate of magnesia is sparingly soluble. It attacks glass in the same way as the seleniate of lime.

Seleniate of alumina is formed by adding bi-seleniate of ammonia to muriate of alumina. It is decomposed by heat giving out its acid.

Seleniate of glucina is insoluble in water.

Seleniate of zirconia is also insoluble.

Proto seleniate of iron. Selenic acid acts with difficulty on iron. When a salt of iron containing the black oxide is added to a solution of an alkaline seleniate, the proto-seleniate of iron is precipitated. This salt is decomposed by heat, and the oxide of the metal is reduced.

The *bi-seleniate* is obtained by dissolving the seleniate in the acid, or by adding the salt of iron to a solution of an alkaline bi-seleniate.

Per-seleniate of iron is procured by double decomposition. It is of a yellow colour, and yields its acid by the application of heat.

Proto-seleniate of copper is obtained by dissolving the protoxide of the metal in selenic acid. It is of a white colour.

The *per-seleniate* may be formed by mixing sulphate of copper and bi-seleniate of ammonia. It is insoluble, and affords its acid by heat.

Seleniate of lead is formed by mixing muriate of lead with seleniate of ammonia in excess. It melts on the application of caloric, and at a white heat it is decomposed, and sub-seleniate is left in the vessel.

Seleniate of zinc is insoluble; the *bi-seleniate* is soluble; the former, when exposed to heat, generates the *sub-seleniate*.

Per-seleniate of tin is a white powder, insoluble in water, but soluble in muriatic acid. It yields its acid by heat.

Proto-seleniate of mercury. Selenic acid, when added to a salt of mercury, containing protoxide, throws down a white precipitate. This salt is decomposed by potassa, the alkali uniting with the acid. Muriatic acid combines with the oxide and a little of the acid, and leaves selenium reduced.

Per-seleniate of mercury is a white insoluble powder. The *bi-perseleniate* is formed by dissolving peroxide of mercury in selenic acid, and evaporating till crystals are formed. When a solution of this salt is mixed with sulphurous acid, proto-seleniate of mercury and selenium are precipitated.

Seleniate of manganese is a white powder, which, when exposed to the air, attracts oxygen, and the acid is disengaged. This salt possesses the property of destroying glass.

Seleniate of silver is white. It is soluble in boiling nitric acid, and when water is added to the solution, it is deposited in acicular crystals. It is composed of

100 acid,
205.75 base.

Seleniate of cobalt is a rose-coloured insoluble powder.

Seleniate of nickel, when dry, is pale green.

Proto-seleniate of cerium is a white powder, soluble in selenic acid, forming *bi-seleniate*.

Per-seleniate of uranium is a yellowish powder, which is decomposed by heat. It is soluble in selenic acid, and forms *bi-perseleniate*.

Seleniuretted hydrogen and bases. The hydro-seleniurets of the fixed alkalies are easiest formed by passing a current of the gas through a solution of these bodies. When seleniuretted hydrogen and ammonia in the state of gas are brought into contact, they combine and form a powder of a pale red colour.

The hydro-seleniurets of lime, baryta, strontia, and magnesia, are soluble. The hydro-seleniurets of the other earths are insoluble.

Berzelius has not examined particularly the properties of the hydro-seleniurets. When seleniuretted hydrogen was passed through lime water, a reddish powder was precipitated. The clear liquor kept in a phial, not well stopped, became red on the surface, which gradually descended, till the whole acquired the same colour. A reddish substance was then deposited, and the fluid became colourless. According to Berzelius, the coloured solution contained seleniuretted hydro-seleniuret of lime. The hydro-seleniurets of the alkalies are likewise decomposed when kept in contact with air, and selenium is separated, forming a pellicle on the surface of the fluid. If the separation of the metal occur slowly, and if the vessel be not agitated, the selenium is deposited in the dendritic form.

All the metallic solutions are precipitated by the alkaline hydro-seleniurets. The precipitates from the salts of zinc, manganese, cerium, and probably also uranium, are hydro-seleniurets. Those from the other metallic salts are seleniurets.

From the properties of selenium we may consider it as more nearly allied to sulphur than to any other substance; at the same time its high metallic lustre and specific gravity would induce us to class it among the metals. Berzelius thinks that it belongs to the division of these bodies, called electro-negative, or those which, by their combination, generate acids; among these are arsenic and tellurium, to which also it seems nearly allied.

It may be considered as another substance added to that class of bodies which generate acids by their union both with oxygen and hydrogen.

Berzelius has found selenium in two other minerals, the one of these is a seleniuret of copper, mixed with carbonate of lime, the other, which was obtained from a copper mine of Skrickerum, he found contained

Cadmium.

Professor Stromeyer, when examining a compound of zinc, prepared at the chemical laboratory of Salsgitter, which was supposed to contain iron, from its acquiring a yellow colour when heated, discovered that this property was owing to the presence of a peculiar metal not previously known, to which he has given the name of cadmium. He has since found this substance in tutia, and in several of the other compounds of zinc. It exists also, according to him, in metallic zinc, though in very small quantity.

Previous to the experiments of Stromeyer, a preparation of zinc from Silesia was thrown aside by the apothecaries for containing arsenic, because, when dissolved in acid, it was found by Roloff to give a yellow precipitate on the addition of sulphuretted hydrogen, which was considered by him to be orpiment. Roloff, however, in repeating his experiments, ascertained that this precipitate was not occasioned by arsenic, but by another metal, not then known.

Specimens of the Silesian oxide of zinc, and of the precipitate, were afterwards sent to Stromeyer, who ascertained that the phenomena presented by this particular oxide, were owing to the presence of the peculiar metal which he had discovered in the compound of zinc prepared at Salsgitter, and to which he had given the name of cadmium.

Cadmium is procured by dissolving the substances containing it in sulphuric acid, and passing a stream of sulphuretted hydrogen through the solution. The precipitate formed, after being well washed, must be dissolved in muriatic acid, and the excess of acid driven off by heat. What remains is dissolved in water, and carbonate of ammonia is added in excess, to dissolve the copper and zinc precipitated by the sulphuretted hydrogen. In this way carbonate of cadmium is obtained, the carbonic acid of which is expelled by heat. The oxide is then reduced by exposing it with charcoal to a high temperature. Cadmium is of a light whitish colour, inclining to grey, very nearly resembling that of tin. It possesses considerable brilliancy, and takes on a fine polish. It is of a compact texture, and possesses also considerable lustre. It is likewise very ductile, and may be beat into thin plates.

The specific gravity of cadmium at 62 is 8.604. After being hammered, its specific gravity is increased to 8 694.

Cadmium, when subjected to caloric, fuses, and on cooling, it crystallises in octahædrons. At a temperature not much exceeding that of the boiling point of mercury, it passes into vapour, which has no peculiar odour, and which condenses in small drops, exhibiting a crystalline structure.

By mere exposure to the air, cadmium does not undergo any change.

When heated in contact with atmospherical air, it takes fire, and forms a brownish yellow oxide.

Oxide of Cadmium. Cadmium has been made to unite with only one proportion of oxygen.

The oxide has a yellowish green colour, which, however, by exposure to heat, becomes yellow. If the application of the heat be long continued the oxide becomes brown. These changes in the colour are supposed to be owing to the difference in the cohesion of the body; for when they are dissolved by an acid, the same compounds are always formed.

The oxide of cadmium does not undergo any particular change by the application of heat to it. When kept at a white heat in a covered crucible for some time, it did not undergo fusion. When heated in contact with charcoal, it is reduced, the reduction taking place at about a red heat.

The oxide of cadmium is composed of

100 cadmium,
14.353 oxygen.

From this it is inferred that the equivalent number for the metal is 69.677, that of oxygen being 1.

Phosphuret of Cadmium. Cadmium combines with phosphorus, and forms a grey-coloured compound, which is very brittle, and has a slight metallic lustre. When put on burning coals, it emits a beautiful flame, and is converted into phosphate of cadmium. Muriatic acid decomposes it with the evolution of phosphuretted hydrogen.

Sulphuret of Cadmium. Cadmium unites with sulphur; the sulphuret is however easiest formed by heating together the oxide and sulphur. It has a yellow colour when cold, but when exposed to heat it first becomes brown, and then crimson. At a white heat it fuses, and on cooling crystallizes in transparent yellow plates. Sulphuret of cadmium is decomposed by strong muriatic acid, with the disengagement of sulphuretted hydrogen. It is composed of

100 cadmium,
28.172 sulphur.

It is recommended as a good pigment.

Chloride of Cadmium is obtained in rectangular prisms, which, when subjected to heat, sublime, and effloresce on exposure to the air. It is composed of

61.39 cadmium,
38.61 chlorine.

Iodide of Cadmium is obtained in hexaedral transparent colourless tables, which are decomposed at a strong heat, and part of the iodine escapes. It is not altered on exposure to the air, and is not soluble in water. It is composed of

100 cadmium,
227.43 iodine.

The oxide of cadmium unites with acids, and forms with these, salts, which are in general of a white colour. It is insoluble in the fixed alkalies. Ammonia, however, dissolves it. It is also soluble in carbonate of ammonia. Cadmium is acted on by nitric acid, nitric oxide being disengaged during the solution. It is also dissolved, though slowly, by sulphuric and muriatic acids, accompanied with the evolution of hydrogen.

The salts of cadmium are decomposed by the alkalies. By the addition of potassa or soda to the solution of the nitrate, the sulphate, or muriate, a precipitate of a white colour is thrown down, which is not soluble in an excess of alkali. The precipitate is supposed to be the yellow oxide, in combination with water, which gives it the white colour. By the addition of ammonia to these salts, the same precipitate is formed, but is dissolved on adding an excess of the alkali.

Sulphuretted hydrogen, and the hydro-sulphuret of an alkali, throw down a yellow precipitate, which, when dried, acquires an orange yellow colour, something similar to orpiment. The precipitate formed in this case is considered a hydro-sulphuret; it is recommended as a yellow pigment, for which, from its durability, it seems well adapted.

Prussiate of potassa, when added to a solution of a salt of cadmium, throws down a white precipitate. Cadmium is precipitated in the metallic state, from a solution of any of its salts by zinc, the precipitate putting on the dendritic form. On the contrary, when a piece of cadmium is put into a solution of a salt of gold, silver, copper, or lead, these metals are precipitated.

Nitrate of cadmium crystallizes in prisms, and is deliquescent. It is composed of

110 acid,
117.50 oxide.

Carbonate of Cadmium is insoluble in water. Its component parts are 100 acid,

292.88 oxide.

Phosphate of Cadmium is also insoluble. When exposed to a red heat it melts into a transparent glass. It is composed of 100 acid,

225.49 oxide.

Borate of Cadmium is little soluble. When dry it is composed of 27.88 acid,

72.12 oxide.

Sulphate of Cadmium is obtained in large rectangular transparent crystals, which are very soluble in water. It is efflorescent, and when exposed to a strong heat is decomposed, and forms a sub-sulphate. The sulphate is composed of 100 acid,

161.12 oxide.

Acetate of Cadmium is soluble and crystallizable.

Tartrate and Citrate of Cadmium are little soluble.

Oxalate of Cadmium is insoluble.

Cadmium unites with other metals, and forms alloys, which are brittle.

The alloy with copper has a slight tinge of yellow. By the application of a strong heat to it the cadmium is volatilized. It is composed of

100 copper,
84.2 cadmium.

When the cadmium does not exceed the one-hundredth part of the copper, the latter is rendered very brittle. As however the cadmium is expelled by the application of heat to the alloy of these metals, there is no danger of brass made with the substances which contain cadmium being injured by the presence of the latter metal.

The alloy with mercury. Cadmium combines with mercury with great facility, and forms a hard brittle alloy, fusible at 167°. It is composed of

100 mercury,
27.78 cadmium.

The alloy with platinum is composed of

100 platinum,
111.3 cadmium.

The alloy with cobalt is brittle, and not easily fused.

Wodanium.

Lampadius, when examining a mineral supposed to contain cobalt, discovered in it a new metal, to which he has given the name of wodanium. The mineral in which this was found has a metallic lustre, and a greyish colour: its specific gravity was 5.192.

Wodanium has a bronze yellow colour; it is malleable, and strongly attracted by the magnet. Its specific gravity is 11.47.

When exposed to the air it is not tarnished; when subjected to heat in contact with the air it is oxidated.

Nitric acid acts on wodanium; and forms a solution which affords colourless needle-formed crystals, which are very soluble in water. By the addition of ammonia to the solution of a salt of wodanium, a blue precipitate is thrown down. The alkaline phosphates and the arseniates do not afford any precipitate.

Prussiate of potassa throws down a pear-grey precipitate.

A piece of zinc, immersed in the solution of the muriate, precipitates a black metallic powder.

The infusion of nut-galls does not cause any change when added to a solution of a salt of wodanium.

Vestium, or Sirium.

According to Dr. Vest, there exists in the cobalt ore of Schladming, in Upper Steiermark, a peculiar metal, to which the name of Vestium has been given.

To procure this metal, the ore, after being freed from its impurities, was mixed with powdered glass, and fused; what remained was digested in nitric acid, and the arsenic which was dissolved was separated by the addition of acetate of lead and sulphuretted hydrogen. Carbonate of potassa was then added, which threw down the oxide of iron. By evaporating the filtered fluid, a flaky substance was separated, which was a salt of vestium. By the addition of potassa to the fluid after filtration, a precipitate fell, which was dissolved in sulphuric acid. To the solution, sulphate of potassa was added, and another portion of the flaky matter was deposited, mixed with a salt of nickel. These were separated in a great measure by washing. To obtain the salt of vestium pure, the matter deposited was mixed with sulphate of potassa, dissolved in water, and crystallized. What was obtained was boiled in a solution of carbonate of potassa, by which a precipitate was thrown down. This was dissolved in nitric acid, the solution was evaporated to dryness, and the residue, after being exposed to a red heat, was washed with cold muriatic acid, and then dissolved in that acid at a boiling temperature. By the addition of potassa to the solution, the oxide of vestium was precipitated free, as Dr. Vest imagines, from the other substances contained in the ore. By mixing the oxide with arsenic, and exposing it to heat, it was reduced, leaving a metallic button, which was brittle, and had a granular texture.

Oxide of vestium is soluble in nitric, sulphuric, muriatic, and acetic acids. The salts formed are soluble in water. The solutions on evaporation afford crystals, which, when acted on by water, deposit the oxide.

Sulphuretted hydrogen, when added to a solution of a salt of vestium, throws down a reddish-brown precipitate, provided there is not an excess of acid present; if there be a superabundance of acid, no change takes place on the addition of sulphuretted hydrogen.

The alkalies afford precipitates with the solutions of the salts of vestium; that thrown down by ammonia is soluble in an excess of the alkali. The carbonate of potassa and of soda precipitate a carbonate of vestium. Carbonate of ammonia separates a white powder from the muriate, but scarcely effects any change on the sulphate.

Sub-borate of soda does not afford any precipitate with a diluted solution of a salt of vestium.

The phosphate, oxalate, and prussiate of the alkalies, throw down white precipitates.

Lime-water, and the infusion of nut-galls, also precipitate a white powder. The same occurs when a piece of zinc is immersed in a solution of a salt of vestium.

Such are the properties ascribed to vestium. The existence of this as a distinct metal has, however, been called in question by Dr. Wollaston, and Mr. Farraday, chemical assistant in the Royal Institution of London, to whom a small piece of the metal called vestium was sent for examination.

Mr. Farraday dissolved the metal in warm nitric acid. The solution, on the addition of nitrate of baryta, yielded a precipitate of sulphate of baryta. Ammonia added to the solution, afforded oxide of iron The fluid, after filtration, was of a bluish colour, and afforded, with prussiate potassa, a white precipitate. These experiments indicate the presence of sulphur, iron, and nickel; the first of which was acidified by the nitric acid, and yielded the precipitate of sulphate of baryta.

By the action of nitric acid on the metal, a blackish substance was left undissolved, which, according to the experiments of Mr. Farraday, contained an arseniate, for when dissolved in an acid, it gave a yellow precipitate with nitrate of silver, and a greenish one with the sulphate of copper.

With the above results, the experiments of Dr. Wollaston agree. These chemists, therefore, assert, that the substance considered by Dr. Vest as a new metal, is merely a combination of sulphur, iron, nickel, and arsenic, and also cobalt, which was indicated in their experiments.

The principal circumstance that led Dr. Vest to pronounce the substance which he obtained from the cobalt ore of Schladming, a new metal, was its not being precipitated from its solution by sulphuretted hydrogen, when an excess of acid was present, but being thrown down when the solution was neutral. This, however, is the case with nickel.

If a new metal, therefore, do exist in the ore of Schladming, Dr. Vest does not seem to have procured it free from the other bodies contained in the ore, nickel, arsenic, and cobalt.

METAPHYSICS.

Metaphysics have been called the *First Philosophy*, or the *Science of Sciences*, as their object is to explain the principles and causes of all things existing, and to supply the defects of inferior sciences, which do not demonstrate, or sufficiently explain, their principles. Metaphysics, says Lord Monboddo, consider the τα οντα η οντα; that is, things, not as the terms of propositions or syllogisms, but by themselves, and as existing in nature, and not as the subject of any particular science, though they be the principles of all sciences, and of all things existing in the universe.

Some have supposed, that metaphysics have derived their name merely from the circumstance of their being placed after the physics of Aristotle, and have laughed at the fancy of giving a name to a science, from its accidental position among the writings of a certain author. The supposition is unfounded, and of course the ridicule misplaced. When Aristotle inscribed his books which treat of the principles of things, των μετα τα φυσικα, it is evident that he had one of two things in view: he must either have meant that the subjects treated of ought, in the order of study, to come after physical researches; or that they were of a higher character, and required higher faculties to comprehend them. In either of these acceptations, the term metaphysics is peculiarly appropriate; and were we to admit that it was imposed originally by the Aristotelians through ignorance, and without any authority from their master, we would certainly say, that it is the most fortunate coincidence of an accidental name with the true nature of the science to be found in the history of scientific nomenclature.

Having vindicated the name from the charge of a spurious origin, we fear that we shall have still greater difficulty in rescuing the science itself from the opprobrium and ridicule into which it has fallen in the estimation of the present superficial generation. We grant that the ancient nomenclature of the science is sufficiently repulsive; and we are not surprized that the readers of reviews, magazines, and novels, should shrink with horror at the following enumeration of heads into which the schoolmen divided the subject: 1. Ontology; 2 Cosmology; 3. Anthroposophy; 4. Psychology; 5. Pneumatology; 6. Metaphysical Theology. This division was unnecessary and useless; it, for the most part, only tended to create distinctions where there was no real difference, and to render a science, which ought to have been explanatory of every other, the most intricate, perplexing, and uncertain; and we should have hailed with pleasure that independence of thinking, which, despising antiquated names, and unauthorised divisions, endeavoured to extend the boundaries of genuine science.

But the spirit of the ancient metaphysicians has not been expelled by such means as these; it has not, like the demonology of the dark ages, yielded to the light of superior knowledge; it has been driven out by fiends more fell and more foul than itself, by ignorance, indolence, and aversion to solid knowledge. Metaphysics are not the only science proscribed by the reigning taste in Great Britain; every thing that has the appearance of profound discussion, if it be connected with mind or with morals, is thrown aside with disgust; and nothing can obtain so much as an examination, if it is not connected with palpable science, or with that vitiated taste which feeds for ever, without being satisfied, on the fungous productions of superficial knowledge. What Johnston said sarcastically of the literature of Scotland. seems to be in a fair way of being realized as to the whole of Great Britain: it will soon be like a city in a siege, where every man has a ration of food, but no one gets a bellyful.

In such circumstances, we cannot expect much attention to be paid to metaphysics, when the subject both labours under a bad name, and requires too much expence of thought for the present frivolous taste of the age. "It is curious to remark," says an eloquent defender of metaphysical science,* "the strange notions which men, who are quite ignorant of its nature, have formed of the *first philosophy*." There are some who seem seriously to believe, that this science serves only to darken and bewilder the understanding; while others suppose, that it consists in the babbling of a pedantic jargon, which constituted the barbarous language of the scholastic learning. If a perplexed reasoner puzzle himself and his audience, we are almost sure to hear his metaphysical subtlety reproved or lamented; and he, upon his part, seldom fails to ascribe the confusion of his ideas to the obscure nature of all speculative doctrines. If a pert rhetorician get entangled in his own sophistries, he is ever ready to accuse himself of having too much of the very logic which he wants. There is not a mere tyro in literature, who has blundered round the meaning of a chapter in Plato, but is content to mistake himself for a philosopher. A sciolist cannot set up for an Atheist, without first hailing himself a metaphysician; while an ignorant dogmatist no sooner finds himself embarrassed with a doubt, than he seeks to avenge his offended vanity, by representing all metaphysical inquiries as idle or mischievous. Thus the noblest of the sciences is mistaken and vilified by the folly of some, and by the prejudices of others; by the impertinent pretensions of a few, who could never understand it, and by the unjustifiable censures of many, who have never given it a fair and candid examination. He, however, who has been accustomed to meditate on the principles of things, the springs of action, the foundations of political government, the sources of moral law, the nature of the passions, the influence of habit and association, the formation of character and temper, the faculties of the soul, and the philosophy of mind, will not be persuaded that these things are unworthy of his patient attention, because presumptuous writers have abused the liberty of investigation, or because dull ones have found it to be unavailing. He knows that metaphysics do not exclude other learning; that, on the contrary, they blend themselves with all the sciences. He feels the love of truth to grow strong with the search

* Sir William Drummond.

of it. He confesses the very bounded powers of the human understanding, while he contemplates the immensity of nature, and the majesty of God; but he thinks that his researches may contribute to enlarge and correct his notions, that they may teach him how to reason with precision, and that they may instruct him in the knowledge of himself. His time, he believes, is seldom employed to greater advantage, than when he considers what may be the nature of his intellectual being, examines the extent of his moral duties, investigates the sources of happiness, and demonstrates the means by which it may be more generally diffused.

We readily grant, that metaphysics have often been grossly abused; they have been disgraced by the uncouth and fantastic dress in which they have been exhibited, or by the perverted purposes to which they have been directed; they have been rendered contemptible by the quibbling of the schoolmen, and by the sophistry and scepticism of Hobbes, Spinosa, and Hume; and we may justly despair of redeeming their credit with those who argue against the general use of any thing from its occasional abuse. Such persons might argue against the benefit of the solar heat, because it is often the cause of pestilence and disease. But we are firmly convinced, that in proportion as intellectual or metaphysical studies are neglected, taste will degenerate, and the general energy of mind will be impaired. That man is a genuine metaphysician, who dives into the nature of things, who methodizes seemingly anomalous facts, and reduces to simple and perspicuous rules, those appearances which present to others nothing but a mass of disjointed and incongruous materials: the man who does this is a benefactor of the human species, and his memory will be honoured as such, while the names of the grovelling herd, who laughed at his pursuits, will be covered with sudden and everlasting oblivion.

How would those who pretend to despise metaphysics have been able to stand before the acuteness of the celebrated sceptics, whose names have been already mentioned? It was necessary that such men as Locke and Berkeley should oppose the dangerous doctrines of Hobbes and Spinosa, on politics, morals, and religion; and that such men as Reid, Campbell, and Stewart, should encounter the dangerous sophistry of Hume. If it should be said, that an instrument so convertible to the best or worst of purposes, had better be kept out of the hands of the generality of men, this is as much as to say, that the power of reason should never be exercised, because it is equally the means of disseminating truth, and of giving currency to error. If any evil consequences have ever resulted from metaphysical discussions, it is only a farther illustration of what has generally been regarded as an axiom, that the corruption of the best things produces the worst effects. Whatever has much power to do good must, if abused, have much power to do mischief; and if metaphysics have occasionally been employed to unhinge belief, or to unsettle the foundations of virtue, it should be remembered, that we derive the means of cure from the same source, and employ the same instruments, but differently handled and applied, to erect the temples of truth, happiness, and virtue.

If mankind knew but where to stop in their researches, metaphysics would appear the most useful, as well as the most sublime science that ever engaged the faculties of the human mind. But they are often brought into discredit, not through any inherent defect in themselves, but from the restless and insatiable desire of the mind to comprehend all mysteries and all knowledge. As this attempt must necessarily prove unsuccessful, we may expect to see the blame laid on the science, which has been employed as the means of investigation. Let man be blamed for attempting impossibilities; but let the science be respected, which will carry him as far as he can go with pleasure and with safety.

Let all the absurdities, then, that have ever proceeded from the brain of a bewildered or sceptical metaphysician, be mustered up to sustain the arraignment against the utility of ontological science, the whole host must instantly give way, before the immortal works which have put them down, by the judicious application of the same principles which less sober or less virtuous men had abused. Is it not in the highest degree ungenerous, then, to remember only the evils which the abuse of the science has produced, without acknowledging the benefits which it has conferred, and feeling grateful for having laid the sure foundations of taste, reasoning, and knowledge? No man will doubt the utility of metaphysical studies, who knows any thing about them, and who is disposed to conduct his researches with that coolness, and philosophic caution, which is necessary to ensure success in any investigation. Let no one, then, be deterred from entering on this study by the outcries of ignorance or prejudice; or by the misrepresentations of those who rail at what they do not understand. *Sicut canes ignotos semper allatrant.* Let those abstain from metaphysics who think that they never ought to grapple with any thing that is profound: let those avoid them, who think that there is no knowledge but what is apprehended by the outward senses: but let those continue to maintain the honour of the science, who wish to explore the recesses and resources of their own minds, who seek to be acquainted with the nature and essential qualities of things, or who wish to know any thing of substance, its attributes, and its adjuncts.

> *Unde anima, atque animi constet natura, videndum,*
> *Qua fiant ratione et qua vi quæque gerantur*
> *In terris.*

But we admit that metaphysics have not only been abused by faulty investigations and unwarranted assumptions, they have also frequently been brought into disrepute by the ridiculous pretensions of some of their advocates. Were we to give credit to Mr. Harris or Lord Monboddo, we should scarcely believe that a man could be confident of the number of his own fingers, unless he were instructed in the metaphysics of Aristotle. What can be more puerile than the observations of the Scottish senator, when he says, that "a mechanic who applies a foot or a yard to the length of two bodies, and finds that both agree exactly to that measure, and are neither longer nor shorter, can give no reason why he believes the bodies to be of equal length, not knowing the axiom of Euclid, that two things which are equal to a third thing, are equal to one another?" (*Ancient Metaphysics*, vol. v p. 154.) Is it not evident, that the mechanic knew the axiom as well as Euclid, and could give just as good an account of it? When he knows the fact he knows the axiom; and he knows, with infallible certainty, that what he has observed in one measurement is applicable to all similar ones; he, therefore, instantly and intuitively adopts the fact as a general principle of knowledge.

We do not know that our readers would thank us, were we to attempt to give a complete system of metaphysics. But, in truth, notwithstanding all that has been done, the attempt is too vast for any individual. Many have elucidated with peculiar success, particular branches of metaphysical science; and they who have attempted more, have, in general, only demonstrated the deficiency of their qualifications, and the futility of their labours. We doubt not, therefore, that our prudence will be approved in declining an undertaking in which so many have failed, though gifted with respectable talents, and armed with high pretensions. We have given in the article Logic, under the head Pneumatology, (which we have considered as embracing Psychology, the most interesting branch of metaphysics,) an account of the origin of our knowledge, of the way in which the mind receives its impressions, of the methods which it employs to communicate its ideas, and of the various circumstances which tend to modify its conceptions. These topics, which might with propriety have fallen under the present article, being already discussed, shall not be repeated. In the article Moral Philosophy also, will be found some important discussions respecting the influence of the will and the affections, and the liberty or necessity of human actions. It is therefore unnecessary to dwell on these subjects here. We shall merely attempt a rapid sketch of what has been done in metaphysics; and this, rather with a view to point out to our readers the subjects and scope of the science, than to require their acquiescence in the doctrines and speculations which have been so elaborately detailed.

Aristotle stands at the head of metaphysicians in point of priority of time, and probably also in point of pre-eminence of intellect. What he fails to elucidate, he envelopes in such a veil of mysticism and perplexing phraseology, that it is scarcely possible to divine his meaning, much less to correct his errors. This circumstance has misled many of his followers and admirers, who, trusting to his infallibility, and convinced that every thing he says must have a profound, if it has not an obvious meaning, have laboured with most indefatigable industry to elucidate his inscrutable researches, and to persuade the world that they contain the substance and essence of all knowledge. The very obscurity which hangs over the writings of Aristotle has tended to increase his fame, and to exalt the reputation of his genius. For ingenious men finding many passages of transcendent excellence in the writings of Aristotle, and many most profound and sublime speculations, have given him credit for a species of omniscience in every kind of science; and whenever any thing occurs which is not very obvious, they uniformly ascribe the difficulty to the profundity of the author's views, and not to the obscurity of his conceptions. Their own minds being at the same time preoccupied by some favourite metaphysical notions, they eagerly watch for any hint in the writings of their idol, which may serve to confirm their own opinion. These hints they may easily find. By disjoining one passage from another, or by connecting remote passages according to their own conceptions, they may make Aristotle speak any language, and lend his suffrage to any set of philosophical opinions. Those passages which are most obscure, will generally answer the purpose best. As they cannot be decidedly claimed as supporting an obvious doctrine, we are ready to feel thankful to any who can attach to them a rational meaning; and we generally find it as easy to assent to it, as to establish a different or opposite signification.

It is, however, but fair to remark, that Aristotle is perhaps scarcely chargeable with one half of the obscurity which now envelopes his writings; and probably also, he is not entitled to full credit for many of the most useful doctrines contained in them. We allude to the vicissitudes which his writings have undergone, and to the mangled and mutilated state in which many of them were found. After having lain in a subterraneous cavern in the town of Scepsis, for 130 years, they were brought to light, and sold to Apellico, a Teian, who, with injudicious industry, supplied from his own conjectures such passages as had become illegible. It is impossible to ascertain the extent of these supplementary emendations, which, in all probability, savoured more of the opinions of the transcriber than of the spirit of Aristotle. But this was not the last ordeal which they underwent. It is well known that they were transferred to Rome by Sylla, after the taking of Athens. Here Tyrannion, a grammarian, having obtained permission to make use of the manuscripts, employed ignorant amanuenses to take copies of them, which he suffered to pass out of his hands without proper correction. These errors have been continued by succeeding commentators and transcribers, who have often introduced into the text conjectural emendations and variations. All ancient writings are liable, in a greater or less degree, to such accidents; but none so much as those which record philosophical doctrines; for here, if there is a possibility of perversion, the commentator or transcriber will endeavour to make the text subservient to his preconceived opinions.

At present, we are only concerned with the metaphysics of Aristotle; and of these we shall give as concise an account as possible. According to him, the fundamental principle of ontology is, that it is impossible that the same thing should be, and not be, in the same subject, at the same time, and in the same respect. To this universal principle all demonstration may be reduced. Being may be reduced into the ten categories, or predicaments, which are, 1. *Substance*, which is either primary, and can neither be predicated of, nor inherent in, any other subject: or secondary, which subsists in primary substances, as *genera* or *species*. 2. *Quantity*, continued or discrete; which has no contrary, and denominates things equal or unequal. 3. *Relation*, expressing the manner in which one thing is affected towards another. 4. *Quality*, by which a thing is said to be such as it is. 5. *Action*, signifying the motion of the agent. 6. *Passion*, signifying the state of the patient. 7. *When*, denoting time. 8. *Where*, denoting place. 9. *Situation*, expressing the external circumstance of local relation. 10. *Habit*, expressing the external circumstance of being habited.

Being is either notional or real; notional, as it is conceived in the mind; real, as it exists in nature. Notional *being* is either true or false; true, when it corresponds to the real nature of things; false, when the conception and the reality differ from each other. In the knowledge of things immutable the intellect cannot be deceived; mistake and error can only arise concerning contingent and variable objects.

Aristotle's notions respecting the first mover were, in some respects, sublime; in others confused and unintelligible. He admitted an original principle of motion, which he said must be simple pure energy, void of matter, eternal, immutable. The essence of the first mover is different from that of corporeal substances, indivisible, because unity is perfect; immutable, because nothing can change itself; and eternal, because motion itself is eternal: (this is a gratuitous assumption.) This power is an incorporeal intelligence; happy in the contemplation of himself; the first cause of all motion; and, in fine, the Being of Beings, or God.

As to the soul, he said that it was the principle of action in an organized body possessing life potentially. It does not move itself, for whatever moves is moved by some other moving power. It is not a rare body composed of elements; for then it would not have perception, more than the elements which compose it. The soul has three faculties, the *nutritive*, the *sensitive*, and the *rational;* the superior comprehending the inferior potentially. The nutritive faculty is that by which life is produced and preserved. The sensitive is that by which we perceive and feel; it does not perceive itself, nor its organs, but some external object, through the intervention of its organs, which are adapted to produce the sensations of sight, hearing, smell, taste, and touch. The senses receive sensible species or forms without matter, as wax receives the impression of a seal without receiving any part of its substance, the external senses perceive objects, but it is the common or internal sense which observes their difference.

He defined the mind to be the principle by which we live, perceive, and understand. When he attempted to form an abstract conception of this principle, he saw that there must be some substance which enjoys such *perfection*, as to be capable of performing this function: and in defining this substance, he made use of a term, which his followers suppose to express some very profound and recondite meaning: he called it *Entelecheia*, that is, *perfection*, or *perfect energy*. This word was conceived to be so very mysterious, that Hermolaus Barbarus, who translated the *Rhetoric*, and other pieces of Aristotle, is said to have implored the assistance of a divinity to enable him to understand its meaning: had he obtained this favour, it is probable that he would have been farther advanced than Aristotle who framed it. It was differently understood by different authors, according as it suited their particular views, and is thus explained by Leibnitz to accommodate his leading hypothesis: *Nomen Entelechiarum imponi possit omnibus substantiis simplicibus seu monadibus creatis.*

Aristotle's metaphysical notions respecting matter were very singular, and we believe we may say incomprehensible. This, of course, is not admitted by adepts, who maintain that he has given us the only intelligible views on the subject. We shall allow the master and the scholars to explain their own ideas Matter, according to Aristotle, is either πρωτη or προσεχης; that is, *primary* or *proximate*. Thus, iron and wood are not of the same proximate matter; but their primary or elementary matter is the same. If the primary matter did not exist, neither could the proximate or immediate. The primary matter is neither earth, nor air, nor fire, nor water; it is neither hot, nor cold, nor dry, nor moist, nor solid, nor extended. It is the universal element, but can never become objective to sense. Spinoza, who was an acute sophist, and a deep read, though we cannot think a profound metaphysician, availed himself of these sublimated, or rather incomprehensible notions of matter, to establish his system of universal materialism, by which he makes Deity himself material. The French philosophists, during the revolutionary phrenzy, went still farther than this; and one of them had the insanity to announce, that he hoped soon to be able to ascertain the particular form of crystallization which constituted Deity! Spinoza, like Aristotle, contended that primary matter, or substance as he calls it, is something completely distinct from any of its modifications, in order to elude the objections which had been urged against his system, from the mutability and divisibility of matter. For it was said with justice, that if Deity was material, the self-existent and eternal principle which Spinoza admitted must be mutable and divisible, which is absurd. Sir William Drummond, in his academical questions, has given a pretty full exposition of the physical and moral system of Spinoza, and has given every advantage to the interlocutor who supports it, without adducing any counterbalancing refutation.

His design in this was singular; for he is any thing but a Spinozist. But as his object is to explode the existence of matter, independent of the perceptions of mind, he seems to wish to terrify his readers into his doctrine, by stating the dangerous consequences which result from admitting the independent existence of matter. The experiment is a little dangerous; for were there no medium between Spinozism and idealism, a good part of mankind might be puzzled how to form a decision. But there is a medium; and whatever difficulties may attend the conception of matter as existing independent of our perceptions, it certainly involves no impossibility.

If our readers find any difficulty in forming a conception of matter abstracted from all its qualities, they shall have the benefit of Mr. Harris's illustration: "We gain a glimpse of it by abstraction, when we say that the first matter is not the lineaments and complexion which make the beautiful face; nor yet the flesh and blood which make those lineaments and that complexion; nor yet the liquid and solid aliments which make that flesh and blood; nor yet the simple bodies of earth and water which make those various aliments; but something which, being below all these, and supporting them all, is yet different from them all, and essential to their existence."

But our elegant author is not content with giving us a glimpse of this subtile and evanescent substance: "We obtain a sight of it, he observes, when we say, that as is the brass to the statue, the marble to the pillar, the timber to the ship, or any one secondary matter to any one peculiar form, so is the first and original matter to all forms in general."

This certainly seems to be pushing matter to the very verge of existence; and, therefore, Sir William Drummond, a keen immaterialist, observes, that we had better pause before we break the bubble of the ideal philosophy, lest it be all that is left to save us from utter annihilation.

The metaphysics of Aristotle formed the text book on these subjects to Europe and the world, for many centuries. The Arabians were as great adepts as the monks of the dark ages. To be able to comprehend and to wield the *Organum* of Aristotle, was considered as the highest attainment in knowledge, and the most desirable accomplishment in literature. It was reckoned presumptuous, and almost heretical, to call his authority in question. Of this we have a remarkable proof in the fate of Peter Ramus, an intrepid impugner of the Aristotelian philosophy. His bold attacks on a system which had been admired for so many ages, gave great offence. His antagonists, however, attacked him at first only with arguments. But finding him refractory, or rather too strong for them, they proceeded to harsher measures. He was accused of an attempt to subvert both religion and philosophy; and though he challenged his opponents to a public disputation, he could not obtain an impartial hearing; and was prohibited by Francis I. from writing or teaching philosophy. This sentence was afterwards reversed by Henry II. and Ramus was appointed regius professor of eloquence and philosophy, and afterwards of mathematics. His enemies, however, became more virulent than ever, when it was found that Ramus favoured the principles of the Reformation. He was obliged to leave France; and after travelling three years in Germany, to visit the principal universities, he unfortunately resolved to return to Paris, where he lost his life by the hand of a hired assassin in the infamous massacre of St. Bartholomew's eve.

But it was the reformation in religion which completed the overthrow of the Aristotelian philosophy. Luther had been early instructed in the Peripatetic doctrines, and in all the subtleties of the scholastic philosophy as taught by Thomas Aquinas, Duns Scotus, and others; and had attached himself to the party of the Nominalists in the dispute about universals. When, however, his eyes were opened to see the errors of the Romish doctrines, he began to question the validity of the principles on which these errors had chiefly rested for support. The result was a thorough conviction of the inutility of the Aristotelian method, and an indignant and contumelious contempt of its quibbles and false refinements. "What does it contribute, says he, towards the knowledge of things, to be perpetually trifling and cavilling in language conceived and prescribed by Aristotle concerning matter, form, motion, and time?" In Luther's ardent temperament, the heat of controversy might easily carry him unwarranted lengths in expressing his contempt for Aristotle's doctrines. He was no enemy to sound philosophy, but he was anxious to free the world from the yoke of authority, both in philosophy and religion.

The defection being thus begun, the revolt soon became general. The method of induction recommended by the powerful genius of Bacon, completely undermined the authority of Aristotle in physical researches; and Descartes soon began to think for himself, and to devise a new method of studying the philosophy of the human mind. The first thing he did was, to dismiss from his mind all reverence for any preceding doctrines and opinions. He went farther still, for he attempted to discard all previous belief which was not established on demonstration. The first point, then, was to ascertain the reality of his own existence; and we should think it would not have been very easy to have done this to the satisfaction of a man who seriously doubted of it. He satisfied himself on this point, however, by reflecting, that what thinks, must exist. *Repugnat enim ut putemus id quod cogitat eo ipso tempore quo cogitat non existere. Ac proinde hæc cognitio, ego cogito, ergo sum, est omnium prima et certissima, quæ cuilibet ordine philosophanti occurrat.* Having thus satisfied himself of his own existence, he next proceeds to examine what evidence he has for the existence of any other object or substance besides himself. He had been accustomed to believe in an external world; on reflection, however, he found that all he knew of that world was in himself; and therefore he was entitled to doubt the reality of its existence; because some superior being might have desired to deceive him. But he is sure he cannot be deceived as to the axiom by which he proves his own existence. *Fallat me quisquis potest, nunquam tamen efficiet ut nihil sim quamdiu me aliquid esse cogitabo.* After the utmost reflection, he finds that he had believed the existence of external objects only *cæco aliquo impulsu*; and he now proceeds to search for arguments. And, first, he satisfies himself that there is a God; for he can form a clear idea of his perfections; perfections which he knows do not exist in himself; but since he entertains the idea of them, there must be an archetype of that idea; and this carries him at once to the Supreme Being, as possessing all the attributes which he had conceived of him.

His reasoning is ingenious, and we shall give it in his own words: "Quia Dei, sive entis summi ideam habemus in nobis, jure possumus examinare, a quanam causa illam habeamus: tantamque in ea immensitatem inveniemus, ut plane ex eo simus certi, non posse illam nobis fuisse inditam, nisi a re, in qua sit revera omnium perfectionum complementum, hoc est, nisi a Deo realiter existente. Est enim lumine naturali notissimum, non modo a nihilo nihil fieri; nec id quod est perfectius ab eo quod est minus perfectum, ut a causa efficiente et totali produci; sed neque etiam in nobis ideam sive imaginem ullius rei esse posse, cujus non alicubi, sive in nobis ipsis, sive extra nos, archetypus aliquis omnes ejus perfectiones reipsa continens, existat. Et quia summas illas perfectiones, quarum ideam habemus, nullo modo in nobis reperimus, ex hoc ipso recte concludimus eas in aliquo a nobis diverso, nempe in deo, esse; vel certe aliquando fuisse, ex quo evidentissime sequitur, ipsas adhuc esse." *Princip. Philosoph. pars prima.*

This is perhaps as good an *a priori* argument for the existence of a God as Dr. Clarke's; and indeed, in some respects, it is not unlike it. Dr. Clarke seems to have borrowed his argument from the following passage in Newton's *Principia*: "Eternus est et infinitus, omnipotens, et omnisciens; id est durat ab eterno in eternum, et adest ab infinito in infinitum. Non est eternitas et infinitas, sed eternus et infinitus; non est duratio et spatium, sed durat et adest. Durat semper, et adest ubique; et existendo semper et ubique durationem et spatium constituit." We would have willingly travelled out of our way, at any time, to exhibit such a sublime specimen of metaphysical theology. Dr. Clarke has made the following use of it: Space and time, he observes, are only abstract conceptions of an immensity and eternity, which force themselves on our belief; and as immensity and eternity are not substances, they must be the attributes of a Being who is necessarily immense and eternal. We shall by and by examine the foundation of this argument.

Descartes having satisfied himself as to the existence of a God, no longer hesitates in acknowledging the reality of an external world; for he concludes that the God whom he serves will not deceive him; as a desire to deceive can only proceed from malice, or fear, or weakness; none of which qualities can ever apply to God.

Descartes adopted the common theory respecting perception. Till his day, and long after it, nobody doubted that certain images were propagated from bodies, in some unaccountable manner, which produced ideas in the mind. Aristotle, as we have already stated, illustrates this, by saying that the senses receive sensible species, or forms, without matter, as wax receives the impression of a seal, without receiving any part of the substance. The received maxim among the Peripatetics, and we do not see how it can be disputed, is, that nothing can act where it is not; and therefore, if matter be different from mind, there must be some medium interposed to bring them, as it were, into contact. This opinion has given rise to a variety of theories half metaphysical, half physiological, such as that of animal spirits, or as the vibrations of Hartley, and the like, with a view to explain the way in which the immaterial substance of the soul is acted upon by external objects. We conceive all such attempts to be futile; nor can we form any conception of contact between a material and an immaterial substance; or of the manner in which body acts on spirit, or this on material substances. An author of some celebrity,* has advanced a very extraordinary hypothesis to explain this mysterious subject; we shall give a part of it in his own words, to caution our readers against the danger of theorizing: "Were I permitted to conjecture in a matter where nothing better than conjecture can be had, I should suppose spirit naturally penetrable, but capable of rendering itself solid upon occasion, with respect to particular bodies, and that hereon our activity depends. I have formerly given my reasons for imagining, that the force wherewith we move our limbs, is derived from the animal circulation rushing into the muscles through certain nerves, and that the orifices of these nerves are provided with stoppers, which the mind draws up at pleasure to give the animal spirits admittance; now what should hinder our conceiving these stoppers pushed up by little hairs, or fibres, whose other ends lie within our spiritual part,† which by its natural penetrability, admits them into the space where it resides? But, upon the mind rendering itself solid with respect to any particular fibre, it is driven forward, thereby lifts up the stopper, and opens the passage into the nerves; until volition, forbearing to act, the penetrability returns—the fibre, no longer pressed, falls back to its former station, the stopper following, closes the passage, and muscular motion ceases."

The author proceeds in the same style; but we have given enough to exhibit a complete specimen of metaphysical absurdity, or rather of the danger which must always attend physiologico-metaphysical speculations.

Locke is by far the most celebrated metaphysician in modern times. There is a perspicuity and good sense apparent in his writings, which insures the attention and good will of the reader. He carefully banished the pedantic phraseology of the schools; and the world was astonished that subjects so profound should be rendered so simple. Even yet he is scarcely considered by some as a metaphysician, solely, we believe, because he employed the language of common life and common sense, in illustrating some of the profoundest points in ontology and psychology. Formerly none but the initiated dared to approach these subjects. They were discussed in a peculiar language, which was as remote from the common conceptions of mankind, and as unintelligible to common understandings, as the signs of free-masonry are to the uninitiated. Socrates was said to have brought philosophy down from heaven: and we may at least say of Locke, that he has brought metaphysics down from the clouds, and planted them in a congenial soil, and reared them with proper culture on the surface of this earth. Perhaps no one ever accomplished so much on such a subject, with fewer errors, and fewer marks of failure. In the article logic, we have pointed out what we conceive to be deficiencies or mistakes in his reasoning;—but we shall have conveyed to our readers an impression very different from our real feelings, if they imagine that we do not entertain the very highest reverence for the genius of Locke, and the highest gratitude for the important services which he has performed, in rendering easy and attractive the science of metaphysics and the study of the human mind.

Descartes had said that the Peripatetic philosophers resembled blind persons, who, in order to equalize the combat with persons who had the use of their eyes, endeavoured to draw them into a dark cavern, where vision could be of no use to them. It is impossible not to admit the justice of the remark, for, if ever there were any who darkened counsel by words without knowledge, this charge may be applied to the schoolmen who adopted the philosophy of Aristotle. No small part of the merit of Locke consisted in sweeping away this useless rubbish, and in teaching mankind to define their ideas and conceptions before they attempted to reason about them.

We are extremely sorry that an attempt has been made in modern times to veil philosophy in her ancient mystery, with a view to exclude her from the profane eyes of the vulgar. This attempt consists not in reviving the phraseology of the Peripatetic school, but in the invention of a set of new terms equally incomprehensible, and equally susceptible of ambiguity and misconception. The author who has made this attempt is Kant, the founder of the *Critical and Transcendental Philosophy*, as it is called in Germany. We have never been fortunate enough to meet with any who pretended to comprehend his system; and for ourselves, we have never yet attempted it. We will be

* Tucker.

† There is a curious coincidence between this wild notion and one advanced by M. Formey, to account for the phenomenon of dreaming. He supposes, like Hartley, that sensation is carried on entirely by means of *vibrations*, which are communicated through the nerves, from the first point of contact till they reach the farthest extremities, which are *dipped* in a spiritual fluid. It is worthy of remark, that this Essay of Formey's is published in the Transactions of the Royal Academy of Sciences and Belles Lettres at Berlin in the year 1746, three years before the appearance of Hartley's Observations on Man. This author, then, has anticipated both Hartley and Tucker. The coincidence is curious; and we should be inclined to suspect them of plagiarism, had the thought been worth stealing. Formey's words are, "Les emanations de ces corps, ou leur parties même heurtants nos nerfs, les ebraolent à la surface de notre corps, et comme lorsqu'on pince une corde tendue, dans quelque endroit que ce soit, toute la corde tremousse; de même, le nerf est ebranlé d'un bout à l'autre, et l'ebranlement de l'extremité interieure est fidelement suivi, et comme accompagné, tant cela fait promtement, de la sensation qui y repond." We cannot help thinking the coincidence between this doctrine and Hartley's too striking to be accidental. Now for Tucker's penetrable spiritual substance: "On con oit de plus aisement que cette extremité interieure est la plus facile à ebranler, parce que les ramifications daos lesquelles elle se termine sont d'une extreme tenuité, et qu'elles sont placées à la source même de ce fluide spiritueux, qui les arrose, les penetre, y court, y serpente, et doit avoir une toute autre activité, que lorsqu'il à fait le long chemin qui le conduit à la surface du corps."

excused for this confession of our ignorance, after the following declaration from Mr. Stewart. "As to Kant's own works, I must fairly acknowledge, that, although I have frequently attempted to read them in the Latin edition printed at Leipsic, I have always been forced to abandon the undertaking in despair, partly from the scholastic barbarism of the style, and partly from my utter inability to unriddle the author's meaning. Wherever I have happened to obtain a momentary glimpse of light, I have derived it, not from Kant himself, but from my previous acquaintance with those opinions of Leibnitz, Berkeley, Hume, Reid, and others, which he has endeavoured to appropriate to himself under the deep disguise of his new phraseology."* This mode of philosophizing deserves to be reprobated and exploded; and we sincerely hope that the German adepts will never be able to make a system of mysticism popular in any country which has been imbued with the philosophy of Locke†.

For some account of the leading principles of Locke's system, and some strictures upon them, see the article Logic. At present, we mean merely to advert to the revolution which his opinions have produced in the philosophy of the human mind; and to the very singular and opposite conclusions to which they have been made subservient. For, on the one hand, they gave rise to the system of Berkeley, Hume, and other idealists, who deny the separate existence of matter, and hold, that what we call by that name is only a modification of thought; whilst, on the other hand, they have given birth, particularly on the Continent, to the material system of Diderot and others, who maintain that mind is only a more refined species of material substance.

It may appear strange that such opposite conclusions should arise out of the same system; but it must appear stranger still, that they are both legitimately deduced from it. That is to say, that Locke, by not sufficiently guarding some of his principles, has afforded room for their being applied or perverted in both these ways. He himself never intended to teach any such doctrines as those which succeeding philosophers and sceptics have deduced from his opinions.

The most celebrated of these systems is that of Berkeley; and we have no hesitation in saying, that it is the most difficult to refute by reasoning. It not only denies the existence of the material world, but affirms that the existence of matter is impossible. Talking of the qualities of matter, Locke had said, that "the ideas of *primary qualities* of bodies are resemblances of them, and their patterns do really exist in the bodies themselves; but the ideas produced in us by these *secondary qualities* have no resemblance of them at all. There is nothing like our ideas existing in the bodies themselves. They are in bodies we denominate from them only a power to produce those sensations in us; and what is sweet, blue, or warm in *idea*, is but the certain bulk, figure, and motion of the insensible parts in the bodies themselves which we call so."

On these data Berkeley builds his system. "They who assert," says he, "that figure, motion, and the rest of the primary or original qualities, do exist without the mind in unthinking substances, do at the same time acknowledge that colours, sounds, heat, cold, and such like secondary qualities, do not; which, they tell us, are sensations existing in the mind alone, that depend on and are occasioned by the different size, texture, and motion of the minute particles of matter. This they take for an undoubted truth, which they can demonstrate beyond all exception. Now, if it be certain that those original qualities are inseparably united with the other sensible qualities, and not even in thought capable of being abstracted from them, it plainly follows that they exist only in the mind. But I desire any one to reflect, and try whether he can, by any abstraction of thought, conceive the extension and motion of a body without all other sensible qualities. For my own part, I see evidently that it is not in my power to frame an idea of a body extended and moved, but I must withal give it some colour, or other sensible quality, which is acknowledged to exist only in the mind. In short, extension, figure, and motion, abstracted from all qualities, are inconceivable. Where, therefore, the other sensible qualities are, there must be these also, to wit, in the mind, and no where else."

Before we advert to the way in which these arguments have been answered, we may take notice of the consequences which are supposed to flow from them. These are thought to amount to nothing less than the unhinging of all belief, and the introduction of universal scepticism. Nothing certainly could be farther from the intention of the amiable and ingenious author. For, in the preface to his Dialogues, he says, "If the principles which I here endeavour to propagate are admitted for true, the consequences I think that evidently flow from them are, that atheism and scepticism will be utterly destroyed; many intricate points made plain; great difficulties solved; speculation referred to practice; and men reduced from paradoxes to common sense."

In fact, nothing was ever so completely misunderstood and misrepresented as the system of Berkeley, and that too by men of some name in philosophy. Berkeley anticipated these conclusions, and, in our opinion, gives a most triumphant refutation of them. To do him full justice, we use his own words: "I am of a vulgar cast," says he, "simple enough to believe my senses, and leave things as I find them. It is my opinion, that the real things are those very things I see, and feel, and perceive by my senses. That a thing should really be perceived by my senses, and at the same time not really exist, is to me a plain contradiction. When I deny sensible things an existence out of the mind, I do not mean *my* mind in particular, but *all* minds. Now it is plain they have an existence exterior to my mind, since I find them, by experience, to be independent of it. There is, therefore, some other mind wherein they exist during the intervals between the times of my perceiving them, as likewise they did before my birth, and would do after my annihilation. And as the same is true with regard to all other finite created spirits, it necessarily follows that there is an omnipotent eternal mind, which knows and comprehends all things, and exhibits them to our view in such a manner, and according to such rules, as he himself hath ordained, and are by us termed the laws of nature."

* An attempt is made to explain Kant's system in the second number of the *Edinburgh Review*. See also Sir W. Drummond's *Academical Questions*, and De Gerando, *Hist. de Systemes*, tom. ii. p. 208, 209.

† See the article Kant, where a general view of his philosophy is given by a gentleman who has *read*, and probably understood his works. Ed.

No man who knows any thing of philosophy can doubt that all this is perfectly possible, and, if received in the way in which Berkeley has explained it, could have no unfavourable influence on the conduct, the happiness, and the hopes of men; and we may affirm, without hesitation, that it is grossly misrepresented, and indeed totally misunderstood by Beattie, when he says, "It is subversive of man's most important interests, as a moral, intelligent, and percipient being; and not only so, but also, if it were universally and seriously adopted, the dissolution of society, and the destruction of mankind, would necessarily ensue within the compass of a month." So thought not Plato, who conceived it possible that life might be a continued sleep, and all our thoughts and sensations only dreams. Beattie seems to have confounded the principles of Berkeley with those of Pyrrho, who also denied the existence of the material world, in the most unqualified sense; so that his friends, as it is reported, were obliged to accompany him wherever he went, that he might not be run over by carriages, or fall down precipices.

We even think that Mr. Stewart, the most candid of all philosophers, has scarcely given a fair view of Berkeley's system, when comparing it with that of the Vedanti school among the Hindoos. "The difficulties," says Sir William Jones, "attending the vulgar notion of material substances, induced many of the wisest among the ancients, and some of the most enlightened among the moderns, as well as the Hindoo philosophers, to believe that the whole creation was rather an energy than a work, by which the infinite mind, who is present at all times, and in all places, exhibits to his creatures a set of perceptions like a wonderful picture, or piece of music, always varied, but always uniform." And again, "The Vedantis, unable to form a distinct idea of brute matter independent of mind, or to conceive that the work of supreme goodness was left a moment to itself, imagine that the Deity is ever present to his work, and constantly supports a series of perceptions, which in one sense they call illusory, though they cannot but admit the reality of all created forms, as far as the happiness of creatures can be affected by them."

Mr. Stewart says, that this creed of the Hindoos has not the most distant affinity, in its origin or tendency, to the system of idealism, as it is now commonly understood in this part of the world; the former taking its rise from a high theological speculation; the latter being deduced as a sceptical consequence from a particular hypothesis concerning the origin of our knowledge, inculcated by the schoolmen, and adopted by Locke and his followers. Whatever difference there may be as to the origin of the ideal system and that of the Hindoos, there can be little doubt that Berkeley's principles led him to nearly the same conclusions. The passage already quoted seems clearly to prove this; for he says, "It necessarily follows, that there is an omnipotent eternal mind, which knows and comprehends all things, and exhibits them to our view in such a manner, and according to such rules, as he himself hath ordained, and are by us termed the laws of nature."

On this system of Berkeley was founded the contemptible scepticism of Hume. We could respect an honest sceptic who erred in his researches after truth. But Hume was not an honest sceptic: he had as little faith in his scepticism as in the creed of his country, and was actuated solely by vanity, in the attempt which he made to unhinge the belief of mankind. It has been beautifully observed by Mr. Stewart, that his aim was, not to *interrogate* nature with a view to the discovery of truth, but, by a *cross-examination* of nature, to involve her in such contradictions as might set aside the whole of her evidence as good for nothing." (*Phil. Essays.*) Berkeley having said, that matter and all its qualities have no existence but in the ideas which are in our own minds, Hume proceeded a step farther, and endeavoured to shew that nothing could exist but the impressions of our own minds; by which argument he wished to sweep away the world of spirits, and the Father of spirits. This is a pitiful sophism, which Berkeley foresaw and obviated. He introduces one of the interlocutors in his dialogues as drawing these very consequences from his principles: "In consequence of your own principles, it should follow, that you are only a system of floating ideas, without any substance to support them; and as there is no more meaning in spiritual substance than in material substance, the one is to be exploded as well as the other." To this the other speaker, who supports Berkeley's principles, answers: "How often must I repeat, that I know or am conscious of my own being, and that I myself am not my ideas, but something else; a thinking, active principle, that perceives, knows, wills, and operates about ideas? I know that I, and the same self, perceive both colours and sounds; and that a colour cannot perceive a sound, nor a sound a colour; that I am therefore one independent principle, distinct from colour and sound; and, for the same reason, from all other sensible things and inert ideas. Farther, I know what I mean when I affirm, that there is a spiritual substance, or support of ideas, that is, that a spirit knows and perceives ideas. But I do not know what is meant when it is said, that an unperceiving substance hath inherent in it, and supports either ideas, or the archetypes of ideas." And afterwards he says, "My own mind and my own ideas I have an immediate knowledge of; and, by the help of these, do immediately apprehend the *possibility* of the existence of other spirits and ideas. Farther, from my being, and from the dependency I feel in myself and my ideas, I do, by an act of reason, *necessarily* infer the existence of a God, and of all created things in the mind of God."

Dr. Reid (whom we have heard called the Newton of pneumatology) admits, that Berkeley's system was perfectly incontrovertible, according to the received doctrines respecting the origin of our ideas. He employs a distinction which Berkeley himself had introduced, and says, that although we cannot have an *idea* of matter, as an *idea* can exist only in the mind, yet we may have a *notion* of it; as Berkeley himself admits, that though he cannot have an idea of God, yet he can have a *notion* of his existence. But Reid says this only to combat Berkeley's pretended demonstration of the impossibility of the existence of material substances: he does not attempt to prove the actual existence of matter, but assumes it as an axiom which cannot be proved, because there is no truth plainer than itself. Now, though we do not pretend to say that Descartes was completely successful in his attempt to demonstrate the existence of a material world, yet we certainly do think him completely successful in demonstrating the *possibility* of its existence. He admits the possibility of Berkeley's system, though no one had then promulgated it to the world; for he says he conceived it possible, that his waking thoughts and sensations might be of the same nature with those which passed through the mind in sleep, which he knew could not proceed from external objects. His maxim being to doubt of every thing till it was proved by demonstration, his first ground of douht as to the existence of the external world is stated in these words: " *Quod nulla unquam dum vigilo me sentire crediderim, quæ non etiam inter dormiendum possim aliquando putare me sentire: cumque illa quæ sentire mihi videor in somnis, non credam a rebus extra me positis mihi advenire, non advertebam. quare id potius crederem de iis quæ sentire mihi videor vigilando. Meditatio sexta.*" This is certainly giving all due advantage to the system which he was to oppose. He then proceeds to state the arguments which induced him to believe that matter might exist. He says, that whatever we can clearly conceive is possible; that we are conscious of certain faculties of the mind, such as sensation, imagination, and the like; but that we cannot conceive these to exist except in an intelligent substance. In the same manner, we are forced to recognize certain powers, such as motion, change of shape, and the like, which we must also consider as belonging to some substance, otherwise they would be inconceivable. But it is evident these powers, of which he have such a clear conception, must belong to corporeal or extended substance; for they are inconceivable as applied to mind.

We are not sure that any thing more satisfactory has been written in answer to Berkeley, than these arguments of Descartes, which were written so long before he was born. In fact, they appear to us to give exactly the same evidence for the existence of matter, as we have for our own existence; and this is, on all hands, admitted not to need a proof. Grant the existence of mind, then, and we think Descartes has approached as near as possible to a demonstration of the existence of matter. We think it proper that he should speak for himself on this subject. " *Præterea invenio in me facultates specialibus quibusdam modis cogitandi præditas, puta facultates imaginandi et sentiendi, sine quibus totum me possum clare et distincte intelligere, sed non vice versa illas sine me, hoc est, sine substantia intelligente cui insint: intellectionem enim nonnullam in suo formali conceptu includunt, unde percipio illas a me, ut modos a re distingui. Agnosco etiam quasdam alias facultates, ut locum mutandi, varias figuras induendi, et similes, quæ quidem non magis quam præcedentes. absque aliqua substantia cui insint possunt intelligi; nec proinde etiam absque illa existere. Sed manifestum est has, si quidem existant, inesse debere substantiæ corporeæ sive extensæ non autem intelligenti; quia nempe aliqua extensio non autem ulla plane intellectio in earum claro et distincto conceptu continetur.*"

Or his argument may be put thus: If we can form an idea of extension, motion, form, &c. which undoubtedly we can, then they may exist; and as they cannot exist in a spiritual substance, they must be attributes of something else; and the only other substance of which we have any knowledge, is that which we call matter. We think this completely oversets Berkeley's argument as to the *impossibility* of material existence.

We admit. however, that it does not amount to a demonstration that matter actually exists, except on Descartes' principle, that every thing which can conceive must, somewhere or other, have an archetype. They who would wish to retain their belief in the existence of the material world, had better not bring it to the hazard of a proof, or we fear Berkeley will be too much for them. Dr. Reid, the most strenuous impugner of Berkeley's system, was once a decided Berkeleian. " I once believed this doctrine of ideas so firmly," says he, " as to adopt the whole of Berkeley's system in consequence of it; till finding some consequences to follow from it, which gave me more uneasiness than the want of a material world, it came into my mind, more than forty years ago, to put the question, what evidence have I for the doctrine, that all the objects of my knowledge are ideas in my own mind?" The truth is, if the existence of matter is not admitted as an intuitive perception, it will be impossible to prove it. Certainly nothing is more incomprehensible than the mode in which material objects communicate sensations to our minds. We rather think Berkeley's system more intelligible than the orthodox opinion; and we would gladly embrace it if we could. But it presents this formidable objection, that, if we are deceived as to the existence of matter, we may be deceived in every thing else; for nothing is more certain.

The fate of Descartes' celebrated axiom to prove his own existence, should teach us to beware of attempting to explain ultimate principles. *Cogito, ergo sum*, he considered as incontrovertible; but it involves a *petitio principii* in the very first step. *Cogito* is equivalent to, *I am a thinking being*, and *ergo sum*, to *therefore I am in being*. Here it is evident that every thing is assumed. The premises imply, that he exists as a thinking being; and then he employs them to prove that he exists at all. The syllogism to which his proposition may be reduced has been justly compared to that ridiculed by Cicero: *Si lucet, lucet: lucet autem: lucet igitur.*

Thus we have seen, that one consequence of Locke's philosophy has been, the denial of the existence of the material world by Berkeley and his followers. This consequence naturally enough arose out of the received doctrine concerning ideas, and particularly from Locke's assertion, that the ideas of the primary qualities of matter were actual resemblances; whilst he admitted, that the ideas of the secondary qualities were only sensations in our own minds. Berkeley easily perceived, that there could be no more resemblance between extension and the idea it produced in the mind, than between the sensation of smell and the object which excited it; and on this he built his system. D'Alembert, though a disciple of Locke, had much more correct views on this subject: he says, that the sensation, by means of which we arrive at the knowledge of *extension*, is, in its nature, as incomprehensible as extension itself. And, in the preliminary Discourse to the *Encyclopedie*, he says, that as there is no relation whatever between a sensation and the object which excites it, or to which we refer it, we cannot trace, by reasoning, any possible passage from the one to the other; and therefore he thinks, that it is by a species of instinct that we are forced across the gulf which separates mind from matter; a mode of reasoning very nearly coinciding with that of Dr. Reid.

We now turn to the consideration of some other inferences deduced by the continental philosophers from Locke's principles, which are the very reverse of Berkeley's ideal scheme. If it is true that sensation is the inlet of all our knowledge, it seems to follow, as a natural consequence, that there can be no ideas in the mind but such as have their orgin in material and sensible objects. At least this is the use which has been made of

Locke's doctrine by the materialists on the continent. We shall see by and by, that other continental writers give a very different interpretation to it.

The doctrine of the materialists, as deduced from Locke's principles, is thus stated by Diderot, in the 6th volume of his works. We use the words of Mr. Stewart with very little alteration, which combine the light of a commentary with the fidelity of a translation. "Every idea must necessarily, when brought to its state of ultimate decomposition, resolve itself into a *sensible* representation or picture; and since every thing *in* our understanding has been introduced there by the channel of sensation, whatever proceeds *out* of the understanding is either chimerical, or must be able, in returning by the same road, to re-attach itself to its sensible archetype. Hence an important rule in philosophy, that every expression which cannot find an external and a sensible object to which it can attach itself, is destitute of signification."

These are certainly most portentous consequences of Locke's doctrine, and such as neither he nor any of his sober admirers ever contemplated. They are made the foundation of the most avowed and unqualified *materialism;* and are employed to persuade us that we ought to reject from the book of human knowledge, every word which does not present a notion copied like a picture or image, from some archetype among the objects of external perception.

Such are the natural consequences of interpreting too literally the maxim of the schools, commonly supposed to have been prescribed by Aristotle, but which was framed in latter times, as a corollary deducible from his doctrine. The maxim, *Nihil est in intellectu, quod non fuit prius in sensu*, when literally understood, must necessarily, we should think, lead to materialism: for it implies that *the senses are the beginning and the end of all our knowledge;* a maxim which might easily be employed to cut up by the roots metaphysics, ethics, and religion. It is unfortunate that these sceptics, who have so eagerly perverted the doctrine, did not attend to a most judicious criticism made by Leibnitz, on the fundamental principle of Locke's system. It is in these words: *Nempe, nihil est in intellectu, quod non fuerit in sensu*, NISI IPSE INTELLECTUS. Had Hume attended to this, he never would have confounded mind with its impressions, nor supposed it possible for them to exist but in a spiritual and intelligent substance.

The error of Hume, as well as of the contintental materialists, who attempt to build their systems on Locke's principles, consists in this, that they view the mind merely as a kind of intellectual machine, or *æsthetical* instrument, which receives impressions something in the same way as a *camera obscura*, with this only difference, that the figures, once introduced, remain as it were in some quiet corner, till, on the introduction of some of their old friends, they start forth to renew their acquaintance. But in all these theories the attention is confined entirely to what may be called the mechanism of perception, whilst no regard whatever is paid to the *perceiving* principle. It would be just as rational to suppose that a clock not only *indicates* the hours, but *perceives* and *calculates* the flux of time, as to suppose that any sensation whatever could arise in a mere material substance; the very conception of which implies that it is insentient. To say that extension, figure, motion, solidity, &c. can ever by any possible combination become susceptible of thought and volition, is as inconceivable, and as utterly repugnant to every principle of sense and reason, as it would be to suppose that a thing may be *itself* and its contrary at the same time; or that a figure may be at one and the same time a square and a circle; or that light and darkness may exist in the same place, and at the same instant. In short, the sceptics confound themselves and their followers, by making the mind itself the *instrument* of sensation, instead of ascribing this office to the organs of sense, with which the body is furnished. So distinct is the mind from the materials furnished by the senses, that we firmly believe its most important feelings are independent of the senses: we mean the feelings of pleasure and pain, which are coeval with our existence as sentient beings, and may be, nay, we doubt not, must be perceived, before the senses are called into exercise. All that the senses do, so far as the mere animal is concerned, is to supply those pleasures which the mind desires, or to remove the uneasiness which it feels: and we have elsewhere supposed, and we think it incontrovertible, that the mind may continue susceptible of pleasure or of pain in the absence of all the external senses. Take away sight, hearing, taste, and smell, will a man then be incapable of feeling pleasure and pain? No. Take away the remaining sense of touch; is he then an insentient mass? No: supply his wants, and he will still be happy, so far as his mere animal existence is concerned.

We have seen some very sober philosophers leading themselves astray with the greatest deliberation on this subject; puzzling themselves to which of the senses they should ascribe pleasure and pain, and the like; evidently supposing all along, that the senses were themselves sentient, and not mere instruments of sensation. When a man sees with a telescope a star invisible to the naked eye, or hears with an ear-trumpet a sound otherwise inaudible, he would not surely say that the telescope sees, or that the trumpet hears: and it would be as improper, strictly speaking, to say that the eye sees or the ear hears: but it is accurate as well as philosophical language, to say that we see with the eye and hear with the ear. Had the sceptical writers attended to this, they never would have confounded the mind with its ideas, and the thinking principle with the instruments which it employs, and the perceptions of which it is conscious.

It is true, indeed, we know matter only by its qualities, and mind by its operations: still, however, we have an irresistible conviction that there is something more than the mere qualities of matter to serve as a *substratum*, in which they must inhere, otherwise matter could not exist; for the qualities of matter are not material, any more than the sensations of mind are sentient. In both there must be an invisible, incomprehensible *substratum;* in the one case, as the recipient of qualities, in the other, of sensations. And we have always been of opinion that, were the question to lie solely between the materialists and the idealists, every philosophical, as well as every pious mind must, without hesitation, give its suffrages in favour of the latter, and cling to them, as the best supporters of the dignity and immortal hopes of man. For we say again, that Berkeley's system is infinitely more intelligible than its opposite, we mean than that which would banish mind from the universe; for in that case matter would be inconceivable.

We must therefore be content to embrace the whole system, and admit the existence of mind and matter as ultimate facts, of which we can give no account, (otherwise they would not be ultimate,) and as therefore referable alone to the sovereign will of him who commanded all things to be as they are. It is sufficient that we know the existence of our own minds by consciousness, and the existence of the external world by perception. Of these two points we are absolutely certain, if there is any certainty in human knowledge; if there is not, it is equally in vain to argue on the one side or on the other. This seems to be the conclusion to which Hume would wish to reduce us; and it is the conclusion of one who ought to be denounced as the assassin of human happiness. To the authors of all such attempts, the words of Seneca are peculiarly applicable. "*Non facile dixerim, utrum magis irascor illis, qui nos nihil scire voluerunt, an illis, qui ne hoc quidem nobis reliquerunt, nihil scire.*"

But here we must observe, that though on the admission of a material world, and of the infallibility of the scholastic maxim, *Nihil fuit in intellectu quod non fuit prius in sensu*, the consequences which Diderot, and the other materialists, deduced from these premises must naturally follow, yet on the scheme of Berkeley the maxim of the schools is perfectly harmless; nay, it is the very foundation of his doctrine: and several of the continental philosophers have adopted Diderot's premises without coming to the same conclusion. In the Transactions of the Berlin Academy for the year 1757, there is a paper by M. Merian, in which he adopts, in their full extent, the very principles which Diderot makes the foundation of materialism, and argues that such consequences by no means follow from them. "If we are once fully persuaded," says he, "that sensation is the foundation of all our knowledge, we have only a single step to advance, to be convinced that all our knowledge consists of sensations. It is even impossible to conceive that our knowledge, being mere sensation in its origin, should ever become any thing but sensation, by any after process. Such a transition would not be a change, but a magical transformation; in consequence of which, sensation must have been annihilated, and a new set of ideas must have sprung out of nonentity."* Nothing can be more decisive than this: yet this author is not a materialist. He seems to adopt the opinion of Berkeley; without, however, mentioning his name, or alluding to his system. For, in a subsequent part of the same paper, he makes the following observations. "The materialists believe that the ground is all their own, when we admit that all the faculties of the soul may be reduced to the senses; and the *spiritualists* think their cause essentially injured by this concession. In this instance, both parties are under the influence of prejudice; for what is that *matter* of which the one is so fond, and the other so much afraid? *Is it any thing else than an assemblage of sensations?* The fundamental error of *materialism* lies in confounding the sentient substance with some of its particular sensations; and the state of the soul with the soul itself. It would be absurd to say that the soul is white, or black, or cold, or hot: and it is not less absurd to say, that it is extended or solid. These are all sensations which the soul feels, but they are not the soul itself: and every one of these sensations I may cease to feel, yet my soul will not, on that account, cease to exist.†

The great error of the French philosophers arose from their excessive love of generalization. Locke had simplified the philosophy of the human mind, by reducing all mental phenomena to sensation and reflection. Sensation is the grand inlet of knowledge; and out of the materials which have thus been introduced into the mind, various compounds are formed, the constituent parts of which have all entered by the senses. The doctrine very evidently points out a farther simplification; for since Locke's ideas of reflection are only modifications of the ideas received by sensation, it naturally enough follows that every idea of the human mind may ultimately be referred to sensation. On these principles Helvetius constructed his system, and referred all the phenomena of mind immediately to sensation, which he calls *sensibilité physique*.

He begins, very unphilosophically, we must be permitted to think, to prove that memory is only *sensation continued*, but weakened. We have elsewhere called memory a kind of *continuous perception*, by which we merely mean the retention of the original idea; but we assign to memory much more important purposes than this: it supplies the place of instinct; and when various objects are presented to the mind, if they have ever passed in review before it at any other time, the memory, by recollecting the qualities of each, enables the mind to form an immediate decision respecting them. But in all this there is no sensation: on the contrary, memory and sensation cannot exist together, on any principle of philosophical propriety: the memory, we believe, merely exhibits the signs of past sensations; and when these happen to excite an uncommonly lively interest, so that the original feelings are reproduced, we could not, in strictness of speech, call that *memory*; it is intense feeling; it is, in the strictest sense of the word, sensation.

To complete his plan, he has only to prove next, that *judgment* is a modification of sensation. And he makes this supposition: A question is agitated, the object of which is to decide, whether Justice or Generosity be the most useful qualities in the ruler of a state? And he attempts to prove, that this moral question is decided on the principle of sensation. For how, says he, would the orator, or the poet, represent this subject? The orator, he remarks, will present

* Si nous sommes une fois bien persuadés que les sensations sont le commencement des nos connoissances; il ne nous reste qu'un pas a faire nous persuader que toutes nos connoissances sont des sensations. Il est meme assez difficile à concevoir qu'avant d'abord é é des sensations, elles ayent pu devenir autre chose; ce ne seroit pas la un changement; ce seroit une transformation magique: il faudroit que la sensation eut peri, et que l'idée qui lui succede eût été tiree du neant; et il seroit faux que toutes nos connoissances prennent leur origin des sens.

† Les materialistes croyent avoir tout gagné quand on leur accorde que toutes les facultés de l'ame se reduisent aux sens; et les spiritualistes croiroient nuire essentiallement à leur cause en faisant cette concession. Prejugé le part et d'autre. On ne prouvera jamais qu'il soit plus facile à la matiere de sentir que raisonner: et puis qu'est ce que cette matiere dont les uns sont si amoureux, et que les autres ont si fort en aversion? Nous ne la connoissons que comme une assemblage des sensations. L'erreur du materialism c'est de confondre l'Etre sentant avec quelques unes de ses sensations particulieres, un etat de l'âme avec l'âme elle meme. Si je suis une sensation, laquelle voulez-vous que je sois? Si je suis un assemblage de sensations, quel assemblage? Il y a autant de raison de dire que je suis le blanc ou le noir, le chaud ou le froid, le dur ou le moû, ou tout cela ensemble, que de dire que je suis l'etendu ou le solide; tout cela c'est des sensations que j'eprouve: c'est ne donc pas moi-même; je ne puis cesser d'être moi; et il n'y a aucune de ces choses que je ne puisse cesser d'être.

to the imagination three pictures: in the one he will exhibit a just king condemning a criminal, and causing him to be executed: in another, he will represent a generous prince, opening the doors of the prison, and striking off the fetters from the criminal: and, in the third picture, he would shew the same criminal, immediately on his escape from the prison, arming himself with a dagger, and murdering fifty citizens. These representations would instantly enable any man to decide that justice was the most valuable quality in a ruler; and that it was real mercy to sacrifice one for the safety of many. Helvetius having thus analysed, as he thinks, the sentiment which ought to arise in the mind, by exhibiting the visible signs employed to represent it, he tells us, in conclusion, that all this is mere sensation.

There is, certainly, here, a gross abuse of language, and a great want of philosophical precision. For our part, were we even to see the assassin plunge the knife into the breast of his friend, we should scarcely think that the sentiment of horror which would arise in the mind could be ascribed to *sensibilité physique*. We would ascribe it to a moral sensibility; and are inclined to think that the physical sensibility of Helvetius is a phrase scarcely admissible in philosophy.

But both he, and many others of the French philosophers, have been misled by the material origin of the words, in which even the most refined, moral, and spiritual ideas of the mind are expressed. We have endeavoured to shew (see Logic) that every word of which language is composed, is originally a picture, drawn from material objects; and that as mind can only be known by certain sensible effects, its operations never can be explained but by sensible images. There is an obvious analogy between the progress and culture of the mind, and many of the objects of external nature; between the growth of our bodies, for instance, and the enlargement of our faculties; or between the progress of our minds, and that of vegetable nature; and therefore the one can be employed to illustrate the other without the smallest confusion, or the least danger of confounding their identity. We talk of *cultivating* the mind, or of *cultivating* a field, without the smallest danger of mistake; and we are as little apt to suppose the mind material from this mode of speaking, as we would be to mistake the respective culture of each; or to imagine that the manure employed to fertilize the fields could be applied to the improvement of the human mind.

We can admit, then, without the smallest fear for the consequences, that even the words which express spiritual ideas have a material origin: they are merely the description of certain visible effects, by which the soul manifests its operations; and, when we talk of a storm, or a conflict in the soul, we are merely borrowing what we conceive to be an analogous representation to make known the troubled state of our feelings.

We may here observe, that though Helvetius adopts the same doctrine with Diderot, as to the origin of our knowledge; yet he is not a professed materialist. He says his doctrine is equally reconcileable with both plans; and he very absurdly alleges, that the existence of the soul as a thinking substance distinct from matter, is a doctrine which could only be established by the authority of the church. This is a very suspicious way of talking; it was very generally adopted by Hume and all the sceptics who had not sufficient courage to avow their disbelief of Christianity, but who brought it forward on all occasions, as patronizing dubious opinions, and as establishing certain doctrines which they affect to spare because they are sheltered by its authority. Thus Hume, in the conclusion of his Essay on Miracles, after having attempted to demonstrate that a miracle was impossible, and therefore could not be believed on any principle of reason, affects to say that it was made quite easy by Revelation, and that there could be no difficulty in believing, when we were thus positively commanded to do so. Helvetius was not distinguished for orthodoxy; but what he says respecting the soul seems rather to be in opposition to Descartes's pretended demonstration of its existence, than to have arisen from any sceptical doubt on the subject. Though he perceived that the subject was, in its nature, not susceptible of demonstration, yet he foolishly imagined that it was necessary to have some authority for believing it, not perceiving that ultimate facts, which admit of no proof, can be strengthened by no authority, but must rest on the evidence of our consciousness or of our senses, according as they belong to mind or to matter. *De l'Esprit, Chap. Prem.*

But it was not merely among the continental philosophers that Locke's doctrines were perverted from their original purpose, and made subservient to a scheme of materialism. The opposite system, indeed, obtained much more eclat in this country, and the abettors of materialism have scarcely acquired a name. Hartley, by his physiological theory of vibrations, seemed to give some countenance to it, though he himself protests, and we believe with perfect sincerity, against any intention of deducing such a conclusion from his hypothesis. This we can easily believe, when we find Malebranche, whose general doctrine certainly approached much nearer to the sentiments of the spiritualists than to those of the materialists, holding exactly the same opinions with Hartley as to the immediate cause of sensation. *La seconde chose*, says he, *qui se trouve dans chacune des sensations, est l'ebranlement, des fibres de nos nerfs, que se communique jusqu'au cerveau.* There could not possibly be a clearer anticipation of the Hartleian hypothesis; and it must also be evident that this hypothesis is entirely unsupported by proof. Hartley says that it is a sufficient proof of the truth of hypothesis, that it accounts for all the phenomena of sensation and perception: for, when the key answers to the cipher, he says, we may be sure that we have found the true one. There is a fallacy in this illustration. When we meet with an unintelligible cipher, and at last discover the means of explaining it, we may be sure that we have found the right principle; it can have no meaning or signification on any other. In the same manner, when we find a piece of mechanism designed for motion, a watch, for instance, standing still, or moving irregularly from the want of some particular wheels, and when we discover at last the wheels which exactly answer the purpose, we are sure they are the right ones.

But these illustrations are totally inapplicable, either to the phenomena of mind or to the laws of nature; for here the machine is not standing still, it is in constant and regular motion: and the question is, not to discover the wheel which is wanting, but the one which principally regulates the movements. Here any wheel in the series may be taken, according to the views and knowledge of individuals; and it will account for the motions of all which depend upon it. But if we inquire what put our first material wheel in motion, we shall find that it either depends on another, or that it derives its motion from a spring, or a weight, or from water, or wind, or steam, &c. Any of these will answer the purpose. In the same manner, the physical phenomena of the universe are equally explicable on the principle of Malebranche, who held that every effect was produced by the immediate interposition of Deity; or of Leibnitz, who maintained that there was a pre-established harmony between cause and effect, in consequence of which they acted together, without influencing each other; or of Spinoza, and the Materialists, who hold that matter is eternal, and possesses in itself the principles of motion; or of Berkeley, who contends that there is no matter, but all that we perceive is a vision of the mind. Each of these philosophers had a *key* which he thought was the right one. Hartley's cipher has neither use nor meaning without the *key*. The phenomena of mind, and of the visible universe, are equally interesting, although the real key should never be discovered.

Hartley's system has been adopted by Priestley and Darwin, who have founded on it a system of materialism. Their views, in establishing this conclusion, were, no doubt, very different. Darwin was regardless of consequences, in following out a philosophical theory, and was not withheld by any religious scruples from dismissing mind from the universe; whilst Priestley was led to imagine that it would materially strengthen his peculiar views of Christianity to suppose the soul material, and naturally perishable along with the body. In the Unitarian sheme which Priestley so warmly espoused, the death of Christ seems to present an insurmountable obstacle; and orthodox Christians ask why it should have taken place, attended by so many circumstances of pain and ignominy, if no object of great importance was to be accomplished by it? Priestley's answer is, that this event took place, that by our Saviour's resurrection the hopes of our naturally perishable souls might be revived, and we might thus be authorized to aspire after immortality. To give currency to this conceit, this precipitate and dogmatic reasoner chose to give up all the natural arguments for the soul's immortality, and to represent it as a material substance, and by necessary consequence, as he imagined, perishable in its nature. By this conduct he threw away many solid advantages, without gaining the shadow of a benefit in return; and his conclusion does not seem necessarily to follow from his own premises. For, even allowing the soul to be material, why should it, on that account, be mortal? If the Almighty could endow matter with the power of feeling, thinking, &c. which Mr. Locke seems to think does not imply an absolute absurdity,* and which Dr. Priestley reasons upon as a thing ascertained, we do not see why we should conclude such a substance to be naturally mortal and perishing. In fact, we believe matter to be as imperishable in its nature as mind itself. We see no process which can give us any idea of the annihilation of matter. We see alteration, decomposition, division, dissolution, and all this without the loss of a single integrant particle of the original mass. We do not, however, mean to say, that either mind or matter are naturally and independently immortal; but this we say, that nothing but the same power which called them into existence can reduce them to annihilation. Yet we hold it absurd to talk of any created substance as naturally and essentially immortal; for, if we might presume to assign any bounds to the power of the Almighty, we would say it was limited by this, that he could not make any created substance independent of himself.

We have perhaps said more than enough of Priestley, who is unworthy of notice as a metaphysician; and whose character as a philosopher must rest on his physical researches. He had an acute mind; but he fell into the error which has misled many incipient metaphysicians; for he thought that he needed only to draw from his own resources; and that, the province of mind being always accessible, he might find in his own stores those materials of knowledge which others seek by painful study in the works of the learned. Such a temper has its advantages; but they are nearly counterbalanced by opposite inconveniences. For whilst, on the one hand, the fearlessness of discussion which distinguished Priestley may occasionally strike out new lights, and lead into a path of investigation hitherto unattempted; there is, on the other hand, a danger that the mind which is unacquainted with what others have already done, may be wasting its strength in pursuing phantoms which have already been hunted down, or in toiling to erect a fabric which has already been constructed. Every metaphysician should be acquainted with the labours of his predecessors: and with their knowledge, combined with his own independence of thinking, he may hope to extend the boundaries of science, and to earn well-deserved laurels, in the ample field presented to him by the *first philosophy*.

Of all the French philosophers, Condillac has obtained the highest applause as a commentator on Locke; and indeed it seems to be chiefly through him that Locke's writings are known in France; at least all the philosophers of that country have, without exception, adopted his interpretation of Locke' doctrine; though they are very far from being agreed as to the consequences which may be deduced from it. "Give me matter and motion," said Descartes, "and I will make a world."—"Give me sensation," Condillac seems to say, "and I will make a man." In his Essay on the origin of Human Knowledge, there is often much ingenuity, but there is fully as much of confident assertion. He lays great stress on attention, and makes it a principal instrument of transforming his ideas of sensation into those which we are accustomed to call ideas of reflection. He seems to have given the cue to Mr. Stewart, and some other succeeding philosophers, to consider *attention* as an original power of the mind; though we think it is neither more nor less than a natural or artificial in-

* "We have the ideas of *matter* and *thinking*, but possibly shall never be able to know, whether any mere material being thinks or no; it being impossible for us, by the contemplation of our own ideas, without revelation, to discover whether omnipotency has not given to some systems of matter fitly disposed, a power to perceive and think, or else joined, and fixed to matter so disposed, a thinking immaterial substance, it being, in respect to our notions, not much more remote from our comprehension to conceive, that God can, if he pleases, superadd to matter a faculty of thinking, than that he should superadd to it another substance, with a faculty of thinking." Book IV. Ch. 3. § 6. 6. We think some of the ideas advanced in this passage unworthy of Locke. According to this way of reasoning, we can never say that we can be sure of any thing, because we do not know the extent of Almighty power. We are surely warranted to say, that nothing can exist which implies a contradiction, that a thing cannot be itself, and another thing at the same time; and we can just as easily conceive, that a thing should be black and white, or hot and cold, or fluid and solid, at the same instant, as that mind should be matter, or that matter should think.

terest lent to the affections. Condillac has also made great use of the principle of association, as the means of effecting a transmutation of sensations into ideas the most recondite and profound. This was also the grand *arcanum* of Hartley's system, which was published after Condillac's *Essai sur l'Origine des Connoissances Humaines*; yet we do not mean to say that it was borrowed from it. It seems to form an unavoidable article in every system which assumes sensation alone as the origin of human knowledge, and therefore may be claimed as common property by all who hold this creed.

This coincidence between the opinions of Condillac and Hartley has been observed by Mr. Stewart; but there is a still more striking resemblance between their physiological theories, which he has not noticed. "I suppose here, and in other places," says Condillac, "that the physical cause of the perceptions of the mind, is the concussion of the fibres of the brain; not that I look upon this hypothesis as demonstrated; but that it seems the best adapted for explaining my thought. If this is not the way they are produced, it must be in some other, not very different manner. *For the brain can be acted upon only by motion.* Therefore, whether we suppose the perceptions are occasioned by the concussion of the fibres, or by the circulation of the animal spirits, or by some other cause, it is all the same to the purpose of this discourse." Nugent's Translation.

But the truth is, that the more we extend our knowledge of the history of philosophy, we will be the more struck with the similarity of opinions, and the apparent want of originality among the different authors. In most cases, these coincidences are the effect of ignorance as much as of imitation: for, not knowing what has been done before them, many writers continue to tread in the track of their predecessors, and think, all the while, that they are enlightening the world with original discoveries.

Mr. Stewart leans towards the opinion of Cudworth, and others, who maintain that certain ideas, which never could enter the mind by sensation, are generated by a process of reasoning, or spring out of the natural resources of the understanding. Cudworth compares the visible universe to a well written book, which conveys both pleasure and information to a cultivated mind, but is totally unintelligible to an ignorant person or a brute. "To the eyes of both the same characters will appear; but the learned man, in those characters, will see, heaven, earth, sun, and stars; read profound theorems of philosophy or geometry; learn a great deal of new knowledge from them; and admire the wisdom of the composer; while to the other, nothing appears but black strokes, drawn on white paper. The reason of which is, that the mind of the one is furnished with certain previous inward anticipations, ideas, and instruction, that the other wants."—"In the room of this book of human composition, let us now substitute the book of nature, written all over with the characters and impressions of divine wisdom and goodness, but legible only to the intellectual eye. To the sense both of man and brute, there appears nothing else in it, but, as in the other, so many inky scrawls; that is, nothing but colours and figures. But the mind which hath a participation of the divine wisdom that made it, upon occasion of these sensible delineations, exerting its own inward activity, will have not only a wonderful scene, and large prospects of other thoughts laid open before it, and variety of knowledge, logical, mathematical, and moral, displayed; but also clearly read the divine wisdom and goodness in every page of this great volume, as it were, written in large and legible characters." This passage contains nearly a summary of Mr. Stewart's doctrine, which he thus briefly explains in his Philosophical Essays. "All our simple notions, or, in other words, all the primary elements of our knowledge, are either presented to the mind immediately by the powers of consciousness and of perception, or they are gradually unfolded in the exercise of the various faculties which characterize the human understanding. According to this view of the subject, *the sum total of our knowledge may undoubtedly be said to originate in sensation*, inasmuch as it is by impressions from without, that consciousness is first awakened, and the different faculties of the understanding put in action." At the same time, he admits that this enunciation is liable to the grossest misconstruction, as is exemplified in the crude notions of Locke's French commentators.

That many important truths, which cannot be traced to sensation, in the sense in which Locke understood the word, gain admission into the human mind, is perfectly apparent, when we consider that mathematical truths are eternal, and necessary, and are forced on the mind by an intuitive conviction, and not in consequence of the experience which we have had of their certainty. This was early perceived by Leibnitz, who says, that if Locke had been careful to distinguish between necessary or demonstrative truths, and those with which we become acquainted by experience and induction, he would have perceived that the former could only be proved by a power of intuition inherent in the human mind; and not by a reference to any knowledge already acquired by the senses. This is a commentary rather than a translation; but we think it sufficiently expresses the sense of the author. *Si Lockius discrimen inter veritates necessarias seu demonstratione perceptas, et eas quæ nobis sola inductione innotescunt, satis considerasset; animadvertisset necessarias non posse combrobari, nisi ex principiis menti insitis; cum sensus quidem doceant quid fiat, sed non quid necessario fiat.*

For our part, though we certainly do not think that mathematical truths can be referred to sensation in the sense in which Locke understands the word; for they derive no confirmation from experience, being as convincing the first time they are presented to the mind, as after a hundred repetitions; yet we think they may find easy access to the mind by perception, in the extended view which we are disposed to take of it. For we maintain, that perception not only makes us acquainted with the existence of external objects, but with those circumstances, which, in process of time, come to constitute mathematical science. By perception, we not only discover the primary qualities of matter, such as extension, figure, &c. but we discover proportion, equality, resemblance, number, relation, analogy, and the like. When equal objects are presented, we see that they agree; when unequal, we see that they differ: and out of a few incontrovertible axioms, which the mind admits the moment they are presented to it, we erect that fabric of mathematical knowledge which is supposed by many to constitute the chief glory of the human understanding. Dr. Reid, on several occasions, seems willing to extend the boundaries of perception, and to allow it all the influence which we contend for; and we have only to regret, that he does not prosecute his views to their legitimate consequences. Towards the conclusion of his *Inquiry into the Human Mind*, he says, "Every operation of the senses, in its very nature, implies judgment, or belief, as well as simple apprehension. Thus, when I feel the pain of the gout in my toe, I have not only a notion of pain, but a belief of its existence, and a belief of some disorder in my toe which occasions it; and this belief is not produced by comparing ideas, and perceiving their agreements and disagreements; it is included in the very nature of the sensation. When I perceive a tree before me, my faculty of seeing gives me not only a notion, or simple apprehension of the tree, but a belief of its existence, and of its figure, distance, and magnitude; and this judgment, or belief, is not got by comparing ideas, it is included in the very nature of the perception."

In the rapid sketch which we have attempted to give of the progress of metaphysical science in modern times, our attention was necessarily led to Descartes as the founder of the modern school of metaphysics. Those who came after him, and who have taken the lead in such discussions, have done little more than modify or alter some subordinate points; whilst the grand pillar of the system, the doctrine of ideas, remained untouched: and Dr. Reid has very justly observed, that the system which, till his time, was generally received, with regard to the mind and it operations, derives not only its spirit from Descartes, but its fundamental principles; and after all, the improvements made by Malebranche, Locke, Berkeley, and Hume, may still be called the Cartesian system. The first of these philosophers must always be mentioned with respect as an original and profound thinker, and as a valuable contributor to the philosophy of mind; though we have not brought him forward in chronological order, having been carried along with the current of dominant opinion, which has thrown his writings aside, and consigned to neglect many elegant and valuable speculations. Indeed, he is so independent that he could scarcely be brought into the train of any other author: and he is so singular that he has had few followers, and has failed to establish himself as the head of a sect. The leading feature in his doctrine is, that the causes which philosophy investigates are only *occasional causes*, and that God himself is the efficient and immediate cause of every effect cognisable by our senses or our reason. It had been stated before his time, that we are completely ignorant of the manner in which physical causes and effects are connected; and that we saw nothing but a constant conjunction, and invariable sequence. This is a doctrine which afterwards brought considerable celebrity to the name of Hume, who is still by many supposed to have been the first who illustrated and explained it. But it was, in fact, unfolded at great length, and with great ingenuity, by Malebranche, whose doctrine of *occasional causes* hinges upon it. He supposed that what we call second causes have no existence, and that the divine power, incessantly and universally exerted, is the immediate cause of all the phenomena of nature. In this conclusion he went farther than his premises warranted: for though we cannot discover any necessary connection between physical causes, and the effects which follow, we are not therefore authorized to conclude that such connections are impossible. At all events, we may safely affirm, that the French metaphysician who introduced the immediate agency of the Deity in every visible change that takes place in the universe, is more fully warranted in his conclusion, than the English sceptic, who, from not perceiving any necessary link between preceding and subsequent phenomena, would have wished to persuade his readers, that they had no ground to infer, from any thing which they saw, the existence of an all-powerful and intelligent first cause. In fact, Dr. Clarke seems to have entertained nearly the same ideas as Malebranche respecting the laws of nature. "The course of nature," says he, "truly and properly speaking, is nothing but the will of God producing certain effects in a continued, regular, constant, and uniform manner."

Malebranche built a theory of perception on the same foundation: for as, according to his system, the agency of the Deity was interposed in carrying into effect every volition of the mind which prompted to bodily action, it was no less natural to conclude, that every *perception* was the effect of an immediate divine illumination. Hence he concluded, that the *ideas* of things exist only in the divine mind, and that *we see all things in God;* a notion which has often been ridiculed, and scarcely ever adopted by any succeeding author; but which bears a strong resemblance to some of the opinions of the latter Platonists, and more particularly to the system of some Hindoo philosophers, which we have already stated in the words of Sir William Jones. According to this system, the universe is to be considered rather as an energy than as a work by which the infinite mind, being everywhere always, exhibits to the minds of sentient beings a set of perceptions like a wonderful picture.

The *occasional causes* of Malebranche were attacked by Leibnitz, to make way for his doctrine of *pre-established harmony* and *sufficient reason.* It was objected that, according to Malebranche, every phenomenon in the universe was a miracle; an objection which is obviated by the regular course of nature; the disturbance or interruption of which constitutes a miracle. We are surprised to find a modern author*, of great metaphysical acumen, joining in the cry against Malebranche, and opposing his doctrine by such arguments as these: "Occasional causes are consistent neither with the omniscience, nor with the omnipotence of God. The acts of the Deity must be supposed as perfect as possible. It is not to be imagined that infinite power is continually employed in sustaining and repairing the tottering fabric of a crumbling edifice—the crazy constitution of the material world. It would, indeed, be to detract from the Divine Majesty, if we admitted this doctrine, and believed that a *curiosus et plenus negotii Deus* was perpetually busied in correcting the errors of his original plan, and in preventing the destruction of his own works." If no better arguments than these can be produced against the system of Malebranche, it may be pronounced to be unanswerable: for they are all drawn from the worst source of reasoning that can be conceived, viz. that of measuring the omnipotence of God by the limited powers of man. The objectors to Malebranche's system represent the universe as a machine contrived and set in motion by the wisdom and power of God, and rendered capable of continuing its operations in consequence of the constitution which it has received from omnipotence. This is to us inconceivable: we do not pretend to comprehend the operations of the Almighty;

* Sir William Drummond.

but we believe his presence constantly necessary for the preservation of every created thing; and that he could not make any thing capable of existing independent of his immediate power: for this would be to communicate his eternity and self-existence; which implies a contradiction: and the principle of *contradiction*, according to Wolff, the disciple and expounder of Leibnitz, is the test of truth.

We can conceive an engine, contrived by human skill, and put in motion by mechanical means, to be perfectly independent of the inventor. A mill, for instance, will continue in motion for ever, unless the materials give way, or the supply of water fail. The principle applied by the mill-wright may be said to be of perpetual operation; and when once employed has no farther dependence on him. But this reasoning is totally inapplicable to the eternal workman, who formed the stars of the heaven, and laid the foundations of the earth. The existence of the materials which compose the universe, and of the laws by which they are mutually affected, depend continually upon the will of him by whom they were created and ordained. He is the only principle of life and motion in the universe; and wherever the laws which he has appointed are in operation, we perceive his agency.

Perhaps Malebranche was precipitate in some of his conclusions; perhaps some invisible agent may be interposed to link together the phenomena of nature. But even admitting the possibility of this, it is only discovering another link in the chain of being which hangs from the throne of the Eternal. In fact, the system of Leibnitz does not appear to be essentially different from that which he opposes; and where it does differ from it, it seems to be worse, and savours more strongly of fatalism than the other does of enthusiasm. We pass over his system of monads, which he has borrowed or stolen from Pythagoras and other ancient philosophers, to consider that part of his doctrine which was intended to meet the arguments of Malebranche. It may be thus abridged: "As we are always able to assign the causes of every event with which we are perfectly acquainted, so we may assume it as true, that every thing exists for a *sufficient reason*; and that if we knew all the facts, we could always tell why every thing happens as it does, rather than otherwise. There being, then, a sufficient reason for every thing, and for the universe itself, that sufficient reason must be found in something. It cannot be found in the course of contingent events, because a contingency does not imply a necessary cause; and where the cause is not necessary, the reason cannot be sufficient, why a thing happens as it does, rather than otherwise. It cannot be discovered in what are called the qualities and substance of matter; because matter is inert, and because every change in its state being induced by a prior change, the series would be infinite, and the ultimate cause could not be found. The sufficient reason, then, which has occasioned the existence of every thing, can only be attributed to some intellectual substance, bearing in itself the reason of its own being, together with the knowledge why all things happen as they do, and not otherwise. This substance accounts to itself alone for all things, since it alone is acquainted with all things. It acts from itself, and for itself; and it ordains the being of atoms, and of worlds, of monads, and of systems, according to laws pre-established by infinite wisdom. This substance is God.

All things, therefore, act with each other, according to that *harmony* which has been *pre-established* by God, and which consequently is universal and necessary. By him our bodies are predisposed to obey the volitions of our souls. By him the individual monad, and the universe itself, were regulated in every vicissitude which they can experience. The soul acts not upon the body, nor does the body influence the soul. Their mutual concurrence was ordained by God himself, who, in regulating the order of worlds, regulated also all that they contain."*

This is certainly a bold attempt to account for the phenomena of the universe; but we cannot perceive a single advantage which it possesses over the system of Malebranche, to which it was opposed. It approaches nearer to fatalism; for, according to the doctrine of *pre-established harmony*, the Deity is supposed to have ordained all motion, and all change which may take place in corporeal substances. The human body acts in conjunction with the volitions of the soul, because it was predisposed to do so from eternity; and our limbs are moved, and our organs of sense are affected, by the immutable decrees of God himself.

This doctrine avoids the interpositions of Deity supposed by Malebranche; it also avoids the notion entertained by the author of the *Système de la Nature*, and other materialists, who maintain, that there is an efficient principle in every cause, which leads of itself, and by its independent influence, to the production of the effect. But it is clogged with difficulties equally perplexing, and consequences equally revolting. We cannot well see how any one can adopt it without admitting, that the Deity is the ultimate cause, if not the immediate instrument, of evil. It might lead to infer, that the Almighty could not be displeased with any action which men may commit, since every action and every volition are pre-ordained and pre-established to accompany each other; and we might suppose, that he organized for the very purpose the hand which should pollute his altars, and the tongue which would blaspheme his name. These consequences certainly were not intended to be deduced from this system by its very profound author; though they may be shewn to result from that harmony which he thought was pre-established for a sufficient reason.

But certainly one leading principle of the Leibnitzian system is not less applicable to that of Malebranche, who would readily have subscribed to the following maxim of the opposite school. "Ce n'est pas dans les corps qu'on peut decouvrir la raison pourquoi ils suivent ces loix plutot que tout autres; elle ne se trouve que dans une etre distinct des corps."

Before we leave Leibnitz and his school, which has never had much influence in this country, we may remark, that they are careful to distinguish between the *reason* why a thing is as it is, and the *cause* of its being as it is. This is particularly developed by Wolff, but it had been noticed by Descartes long before: "There is nothing which exists," says that philosopher, "respecting which we may not inquire into the *cause* of its existence. Such inquiries may be extended to God

* Academical Questions, p. 326.

himself; not that he needs any *cause* of his existence, but because the very immensity of his nature is the *reason* why he cannot have a *cause* of his existence. Sir William Drummond has, with much learning, traced the monads of Leibnitz up to their Pythagorean source, through all their windings, as discoverable in the writings of Hipprocrates, Stobæus, Sextus Empiricus, &c. and has shewn how largely the German philosopher has availed himself of the scattered fragments of Grecian ontology, which occur in the rarer and less accessible authors; we must therefore transfer to his learning whatever deductions we may be disposed to make from his originality. But his doctrine of sufficient reason is also borrowed; and its original may be found in the forty-sixth chapter of Plato's Phædon. Socrates is introduced as saying that he was delighted, when he found that Anaxagoras had assumed mind or intelligence as the origin of all things. He conceived, that this principle would be sufficient to account for any thing being as it is; because, if mind orders all things, they must be disposed in the situation and order which is best; and that if we wish to know why any thing is produced, or is destroyed, or exists as it is, we have only to inquire in what respects these several accidents and circumstances are most befitting in the cases in question. If any thing, for instance, happens to man, he is to consider that this, being regulated by supreme intelligence, must be the best that could befal him, and he has only to inquire in what respects it is best for him. In the same manner, after inquiring whether the earth be flat or round, the next point is to shew, in what respects that figure is best adapted to it. Were these things once properly settled, Socrates conceived that he would then have discovered a *sufficient reason* for the existence of things as they are, and that it would be unnecessary to search any farther into their causes.* We may easily perceive, then, that the doctrine for which this prince of philosophers expressed a partiality agrees, in many respects, with the *sufficient reason* of Leibnitz, and also with the doctrine which Pope undertook to illustrate without understanding it, that "whatever is, is right."

On a general view of the subject, we may distinguish three grand æras in the history of metaphysics, very unequal in point of time, but each of them marked with a very distinct and decided character. The first extends from the time of Aristotle to that of Descartes. During the currency of this long period, many persons arose, distinguished for metaphysical acumen, who attacked successfully some of the outworks of the Aristotelian doctrine; but they made little or no impression on the general scheme, and Aristotle continued the undisputed sovereign of metaphysicians. Lord Bacon gave a deadly blow to his empire, and was the first who shewed, in detail, the inutility of his method for the discovery of truth. Whether Descartes caught the spirit of Bacon, (if he did, he does not acknowledge it; for we do not recollect that any allusion is made to Bacon in any part of his works,) or whether the strength of his genius led him to assert the same independence of thinking, we know not; yet certain it is, that he introduced the same unfettered discussion into metaphysics, which Bacon had applied so successfully to the interpretation of nature. His method was both clear and original; and, in spite of the attempts which were made to resist it, it soon obtained possession of the schools, and drove Aristotle from the throne which he had occupied for so many hundred years. All the succeeding philosophers of any name were Cartesians; and Locke himself belonged to the same school, as has already been observed. But he served his master in the same way that he had done Aristotle, by pushing him from the seat of philosophy; and so complete was his victory, or his usurpation, that the name of his illustrious predecessor is now seldom mentioned as an authority in metaphysical science. But we certainly think it but justice to Descartes to say, that no man ever borrowed less from his predecessors. His whole efforts were directed to emancipate his mind from every prejudice, and to come unbiassed to the investigation of truth. There were some absurdities, however, connected with his doctrines, such as his *vortices* and innate ideas, by which he understood those ideas which he perceived could not enter by the external senses, and which he therefore supposed to exist in the mind previous to their exercise; these notions, as well as many other unauthorized assumptions, which were industriously exposed by his opponents, brought discredit on his doctrine, and prepared the world for the cautious and sensible system of Locke; who, rejecting what was false, or unwarranted, and retaining, explaining, and amplifying what was useful, justly merited the name of the founder of a new school in philosophy.

It was for a long time supposed that he had pre-occupied the ground as a metaphysician and pneumatologist, as completely as Newton had done in mathematics and natural philosophy. Indeed our brethren in the South seem, in general, to be still of the same opinion; and such of them as have extended their views a little farther, have not ventured to go beyond the speculations of Hartley. In short, England has been most exceedingly barren in metaphysicians, especially in later times; and had it not given birth to Cudworth, and Locke, and one or two more, it would scarcely have been known throughout Europe to have ever harboured the philosophy of the human mind. The northern part of our island has been much more productive in this species of literature; and the *Scotch school* has obtained a name on the Continent. Scotland has reason to be proud of this distinction; and its inhabitants are likely for a while, at least, to enjoy their laurels undisturbed, unless they are annoyed by the affected sneers of their neighbours at Scotch metaphysics, which, since the days of Hume, have been represented as synonymous with scepticism.

Reid deservedly takes the lead, as having brought about an important reformation in philosophy. He has

* Ακουσας μεν ποτε εκ βιβλιου τινος Αναξαγορου αναγιγνωσκοντος, και λεγοντος ως αρα νους εστι ὁ διακοσμων τε και παντων αιτιος, ταυτη δη τη αιτια ησθην τε, και εδοξε μοι τροπον τινα ευ εχειν, το τον νουν ειναι παντων αιτιον· και ἡγησαμην, ει τουτο ὁυτως εχει, τον γε νουν κοσμουντα, παντα κοσμειν, και εκαστον, τιθεναι ταυτη, οπη αν βελτιστα εχη. κ. τ. λ. Socrates, however, expresses his extreme regret at the disappointment of the high expectations which he had formed, when he first heard of Anaxagoras having introduced mind as the principle and disposer of all things. For he says that he did not find him treating of one of the subjects on which he wished to be informed, but bringing in aërial, etherial, or watery fluids to account for the constitution of things; and as the causes of the various phenomena which they exhibit.

not only corrected many mistakes of Locke; but he has endeavoured to explode the whole doctrine of ideas, which prevailed from the time of Aristotle till it was attacked by the Scotch philosopher. According to this doctrine, nothing can be present to the mind but an idea, which is supposed to be some kind of representation of the object from which it proceeds. It is not enough that the senses be affected in a particular way; the only result of such affection is the production of an idea, and this idea alone is perceived by the mind. Our readers must recollect, that when the Cartesians speak of *ideas*, they use the word in a sense quite different from its ordinary acceptation in our language. They understood an *idea* as a representation transmitted to the mind through the senses, and which communicates an impression without imparting any portion of its substance. This is the philosophical meaning of the word *idea*, as employed by Locke and all the Cartesians. In our language, it is now considered as synonymous with *notion* or *conception*.

The doctrine of *ideas* which had kept possession of the schools for upwards of two thousand years; (for it did not originate with Descartes, he only explained and illustrated it more fully than had ever been done before:) this doctrine originated in an attempt to solve the difficulty which has always been felt in understanding how material objects can make an impression on a spiritual substance like the soul; and, instead of being founded either on observation or induction, it rests on the flimsy basis of unwarranted analogies. It was thus illustrated by Aristotle and his followers: As wax receives the impression of a seal without the substance of the seal, or as a looking-glass receives the images of objects which are at a distance from it; in the same manner, the mind receives the representation of things which cannot penetrate it, or which may be at a distance from it. Such is the only foundation of the doctrine of ideas; and never, certainly, in the history of the world, did such momentous consequences arise out of a mere analogy. For many ages it filled the world with systems of philosophy; till at last it banished from the world every thing but ideas and impressions.

We admit that, in many instances, analogy is a legitimate ground of argument. When we meet with positive facts, which at first seem insolated, and not reducible to any general rule, we anxiously look around us for illustrations, under the firm conviction that the whole system of nature is linked together by indissoluble connections; and that nothing can appear separate and detached, except from our ignorance of its affinities and relations. When at last we discover a number of similar appearances, and perceive that become general which, at first, we reckoned singular and anomalous, we conceive that we have received a sufficient explanation, and have discovered a law of nature hitherto unknown. This, indeed, is the foundation of all sciences, except such as rest on axioms or necessary truths.

Had any one, then, been sensible of an image depicted on his mind, in the same manner as it is presented in a looking-glass, he might have fairly concluded that he had advanced a step in explaining the phenomena of perception. But we are conscious of nothing but sensations, which, in general, we can refer to certain organs; but beyond that every thing is inscrutable; and we may say of sensation what St. Augustine said of time, *Si non roges, intelligo.*

There is another circumstance which has misled philosophers on this subject. In vision, for instance, an actual picture is painted on the *retina*, and when this picture is not produced, there is no perception of visible objects. This lends some countenance to the opinion, that an actual picture must be presented to the mind in every act of perception. This is the most favourable example that can be produced in support of the doctrine of ideas; and yet we do not see that it advances our knowledge a single step as to the real nature of perception. We have got an additional preliminary fact; but we can scarcely be said to be nearer to ultimate knowledge; and the optician or phisiologist who is most intimately acquainted with the structore of the eye, knows no more of the nature of perception, than the clown who never heard of its lens, or coats, or humours.

They who have attempted to combine physiology with metaphysics, have endeavoured to penetrate a little farther behind the scenes, and have carried the image from the *retina* to the brain by means of the optic nerve. They have, no doubt, some grounds for this process; for when the optic nerve is destroyed, no sensation is produced. But it is quite clear that the image on the *retina* cannot be transmitted through the nerve on any principle of optics or mechanical philosophy. The picture on the *retina* is exactly the same as that which is produced by means of any lens similarly constructed: and even supposing it carried, by any process, to the brain, we still know no more of perception than we did before. For why should the mind be able to perceive this image, rather than the object itself from which it proceeds?

But, then, it is argued, that as we know for certain, that external objects cannot be present to the mind; (because the mind itself perceives that they are at a distance;) there must be some representations, or images of them, present to the mind, since a thing cannot act where it is not. Here again the principles of mechanical philosophy are brought in to explain a subject to which they are entirely inapplicable. It is said, indeed, that our senses are adapted for the communication of certain sensations. Taste, smell, sounds, are confined to particular organs; and without these organs, we can have no conception that such sensations could be excited: yet these sensations, as well as every other, are mere affections of our minds, bearing no conceivable resemblance to the qualities in external nature which produce them. Taste, and smell, and sound, are no more like any thing we perceive in the qualities of matter, than the written characters in music are like the melodious tunes which they represent.

We hold, then, that the affections of the senses are mere signs, or signals to the mind, to excite certain susceptibilities, or to call into exercise certain faculties. This perhaps might be admitted by all parties, upon allowing them to fix their own interpretation upon it. The Peripatetics and Cartesians would say, that the signs call the mind to the consideration of the subject, in the same manner as the picture of an acquaintance brings him to our recollection: whilst others would say, that they are *arbitrary* but *invariable* signs established by the author of our nature; bearing no kind of resemblance to the things which they represent, yet exhibiting them to the mind as infallibly, as the arbitrary characters of a known language convey to our minds an idea of the sentiments which they represent. The only difference between the two cases is this: that in the one, the signs are fixed by God, and are immutable; whilst in the other, they are selected by ourselves, and may be altered or varied at pleasure.

We venture, then, to call the intimations of our senses *natural characters*, which the author of our being has established as the *indices* of certain sensations: and there is, perhaps, about the same connection between the signs and the things signified, as there is between a smile and the feeling of happiness. A smile is not an artificial sign: (at least we dislike it very much when it assumes this character:) we are irresistibly impelled, by the constitution of our nature, to express certain feelings by certain modifications of the features.

> *Format enim natura prius nos intus ad omnem*
> *Fortunarum habitum; juvat, aut impellit ad iram,*
> *Aut ad humum mærore gravi deducit et angit:*
> *Post effert animi motus interprete lingua.*

There is nothing left to accident here: every thing is fixed and determined; and a man generally makes a very awkward figure when he endeavours to exhibit the signs of emotions different from those which he actually feels. Yet, can any possible connection be traced between the feelings of happiness, or grief, or anger, and a particular modification of the muscles of the face? It is to no purpose that we are told, that certain emotions put in action certain muscles about the heart, we shall say; and that these muscles affect others which, in their turn, communicate the impulse, till the result is depicted in the human countenance. This is, no doubt, a very interesting subject of study to the anatomist or physiologist; but it is perfectly useless to the metaphysician who is enquiring into the origin of sensations, and the connection between natural organs and a thinking spiritual substance. All that the anatomist does is to describe the machinery; the metaphysician endeavours to ascertain the principle of motion.

But, then, some metaphysicians affirm that the perception of objects is not immediate; but that the rapidity with which we interpret the signs is the result of early and deep-rooted association. This is the opinion of Hartley and of many others. Dr. Porterfield says, that "it is not the external sun and moon which are in the heavens that our mind perceives, but only their image or representation impressed on the *sensorium*." Perhaps we do not perceive any of the objects of nature as they really are; yet this does not interfere with our ready and rapid apprehension of them. The picture of objects always appears inverted on the *retina*, yet we always perceive them in their right posture. Philosophers and physiologists have puzzled themselves exceedingly to account for this; but all to no purpose. They talk of the rays which proceed from the object, crossing each other in the eye, so that those which come from the upper part of the object strike on the under part of the *retina*, and *vice versa;* and therefore they imagine that we perceive objects in their right posture, in the same manner as we would judge an object which strikes the roof of a room to come from below. This is egregious trifling; was any man alive ever sensible of any crossing of the rays, or of any impulse either on the upper or under part of the posterior coat of the eye? The truth is, that in tracing the image to the *retina*, we are attending only to one stage of the process. We can form no conception whatever of what takes place afterwards; nor can we conceive how it should be easier for the mind to apprehend the image of an object than the object itself.

It is said, indeed, that there must be a communication between the object and the mind. Correctly speaking, we can form no conception of any connection except between the outward object and the bodily senses. Hearing is produced by undulations or pulsations of the air on the ear; taste by the application of sapid substances to the palate; vision by a picture on the eye, &c. Here, then, we perceive an evident connection between external objects and the organs of sense: but still the distance between the impressions on our organs and the sensations of our minds is immeasurable; and we consider it as perfectly unphilosophical to talk of either an object or any image being present to the mind. Who can fix the locality of a spirit, or say that it can even be in contact with a material substance? Or how can a spiritual substance be affected by any thing but a spirit?

These are questions which no man can answer; yet we see that particular objects produce, with infallible certainty, particular sensations in our minds. But these impressions on our senses are merely signs established by the author of our nature to call our attention to objects which it is our interest to pursue or avoid, and which may promote or impair our happiness.

By following the train of our own conceptions, we have been led to some conclusions not very remote, we apprehend, from the opinions of Malebranche and of Leibnitz: for though their systems are professedly opposed to each other, we do not see that they differ widely on the point in question. But all that we mean to say is this, that after examining, with the utmost minuteness, the mechanism of the senses, and showing the organic affection which takes place when a sensation is produced, we are as far as ever from being able to connect mind with matter, or to ascertain the way in which they mutually affect each other. Such an intercourse, however, is established by the author of our nature: but there is no chance that we shall ever get behind the scenes, so as to be able to discover every part of the machinery, till *we have shuffled off this mortal coil;* and our souls are disengaged from the gross encumbrances, which at present clog and impede their operations.

All that we know for certain, is, that when impressions are communicated to the senses, they are at the same instant imparted to the mind: and we conclude that this is done *immediately*, how complicated soever the machinery may be which is put in motion by the external impression. When, for instance, we handle a cube, or a globe, we receive *immediate* intimation that we are handling an extended substance, distinct from our own bodies. There is not the most distant foundation for the supposition of any image being interposed to make the object apprehensible by the mind; and we do not see that it makes any material difference, though the objects be placed at a distance; they are still connected with the senses by certain sensible *intermedia*, which bring them into contact, when an immediate perception is produced in the mind. We conclude, then, without the smallest hesitation, that *external existence is the immediate object of perception*, and not the result of associations, or of the interposition of images or ideas, of which no man was ever sensible.

In short, we do not think that there ever was a philosophical dogma which, with such a slight foundation, exerted such influence over the human understanding.

It is, at least, as old as Plato, perfectly conformable to his poetical genius, which delighted in analogical and metaphorical illustrations. He supposes a man to be lying bound in a dark cave, into which some rays of light are admitted through an aperture. These rays fall on the side of the cave to which the eyes of the prisoner are directed. In the meantime, a number of persons or objects, in passing, intercept part of the light, and their shadows are cast on the opposite side of the cave. These shadows, and not the things themselves, are perceived by the prisoner. In the same manner, Plato conceived that the senses perceive not the things themselves, but only the images of them. It is evident that all this is mere fancy; yet we do not think that the doctrine of ideas has any better foundation to support it.

Descartes, like all the old philosophers, took it for granted, that what we perceive must be either in the mind itself or in the brain, to which the mind, as he supposed, is immediately present: for this purpose, he fixed the seat of the soul in the *pineal gland*. If objects are perceived in the mind, Hume argues fairly enough, that the mind must be extended; for we cannot conceive how the *idea* of extension, (which, according to Descartes and his followers, is an image of the original,) can ever be *in* an unextended substance. And, as for the *seat of the soul*, were not the subject now exploded, we would recommend it to the ridicule of the poet, rather than to the discussion of philosophers. At one time, however, it occupied no small space in their speculations, and is thus ridiculed by Prior in his *Alma*.

———————" Here Matthew said,
Alma in verse, in prose the mind
By Aristotle's pen defined,
Throughout the body squat or tall,
Is, *bona fide*, all in all.
And yet, slap dash, is all again
In every sinew, nerve, and vein;
Runs here and there, like Hamlet's ghost
While every where she rules the roast.
This system, Richard, we are told,
The men of Oxford firmly hold:
The Cambridge wits, you know, deny
With *ipse dixit* to comply.
They say, (for, in good truth, they speak
With small respect of that old Greek,)
That, putting all his words together,
'Tis three blue beans in one blue bladder.
Alma, they strenuously maintain,
Sits cock-horse on her throne, the brain;
And, from that seat of thought, dispenses
Her sovereign pleasure to the senses."

Dr. Reid had the honour to be the first who called in question the Cartesian doctrine of ideas; and, in our opinion, his success has been complete. We have adopted his conclusions without adhering to his train of argument; for we think his opinions need only to be known, to derive illustration from a thousand different sources. We make no pretensions, then, to any discoveries of our own on this subject: we were trained in his doctrines under his illustrious pupil; we therefore lay claim to nothing but the illustration and even this coincides in many instances, as might be expected, with that of Reid.

We have said that the impressions made on the senses are merely signs which the mind interprets with infallible certainty. These signs, Dr. Reid remarks, are the language of nature to man: and, as in many respects it has great affinity with the language of man to man, so particularly in this, that both are partly natural and original; partly acquired by custom. Our original or natural perceptions are analogous to the natural language of man to man; and our acquired perceptions are analogous to artificial language, which, in our mother tongue, is got very much in the same manner with our acquired perceptions. When we perceive that this is the taste of cyder, that of brandy; that this is the smell of an apple, that of an orange; that this is the noise of thunder, that the ringing of bells; this the sound of a coach passing, that the voice of a friend; these perceptions, and others of the same kind, are not original, they are acquired. But the perception which we have by touch of the hardness and softness of bodies; of their extension, figure, and motion, is not acquired, it is original.

" Experience teaches us, that certain impressions upon the body are constantly followed by certain sensations of the mind; and that, on the other hand, certain determinations of the mind are constantly followed by certain motions in the body; but we see not the chain that ties these things together. Who knows but their connection may be arbitrary, and owing to the will of our Maker?" Such are the words of Dr. Reid; and we think he need have no hesitation in declaring, that every thing which depends on the will of the Almighty, as sensation, and every thing else undoubtedly must, is most certainly arbitrary, and determined by nothing but his own free will. This is nearly an identical proposition: and it is certainly the most obvious of all truths, that whatever the Almighty does, he does it because he wills it. This is equally true of man: but there is this difference in the general result, that the will of Deity never can be influenced by extrinsic motives; for he is all-sufficient and independent; and contingent motives in his case are wholly incomprehensible. Every thing is different, in this respect, with regard to man; he does what he wills, but his will must necessary be influenced by various motives over which he has no control.

Those things which appear natural to us, must be arbitrary to God: we call that natural which continues to retain the qualities, and present the appearances which we have been accustomed to observe in it. We refer, then, both the natural signs of our sensations, and our power of interpreting them, to the will of our Creator, who had only to say, " Let such things be, and such qualities exist," and forthwith the connections which we see were established; which may be called *necessary connections*, inasmuch as they must necessarily continue till the will of the Almighty shall change or suspend them.

Dr. Reid farther observes, that " we know nothing of the machinery, by means of which every different impression upon the organ, nerves and brain, exhibits its corresponding sensation; or of the machinery by means of which each sensation exhibits its corresponding perception. We are inspired with the sensation, and we are inspired with the corresponding perception, by means unknown. And because the mind passes immediately from the sensation to the conception and belief of the object which we have in perception, in the same manner as it passes from signs to the things signified by them, we have therefore called our sensations *signs of external objects*."

We have stated the doctrine a little differently; and have made the impressions on the organs of sense *the* *signs* by which certain sensations in the mind are excited, and by which its attention is, at the same time, directed to the exciting cause. We might have had all the sensations which we now possess, those arising from touch excepted, without any knowledge of an external world. By the experiments first made by Cheselden, and subsequently confirmed by many others, it appears that visible objects, when first presented to the eye, do not appear *external* to it; they seem to be in it: they present merely a variously coloured picture to the mind. In the same manner, sound is a mere sensation; habit alone enables us to judge of the quarter from which it comes, and of its being referable to external causes. If any man will stand blind-folded in the middle of a room, and allow his most intimate acquaintances to walk repeatedly round him, without speaking, and afterwards stand still and address him, he will not know, for several trials, the position of the speaker. It is evident, too, that it is only by experience that we learn to refer smell to odoriferous particles, issuing from external bodies; and that we might have had the sensations of taste without the application of sapid substances to the palate; for nothing is more common than to have a particular taste in the mouth, without being able to ascribe it to any external cause. Nay, it is habit alone which makes us refer particular sensations to particular senses; and, were it not for this, we could have no conception of any existences but our own sensations; excepting always the sensations which arise from touch, and which lead us at once to the conception and knowledge of something external.

In short, we conceive the mind to possess in itself all those capabilities which are roused by an excitement applied to the senses; but we cannot tell how: this only we believe, that it is immediate and instantaneous, however complicated the machinery may be which is interposed. Who can tell how many muscles must be put in motion before a smile or a frown can be depicted on the human countenance? Yet the sensations of joy or anger are no sooner felt, than a visible portraiture of them is displayed on the countenance. To account for the explosion of gunpowder by the application of a spark of fire, would require a complete knowledge of pneumatic chemistry, and of the constitution and properties of the atmosphere: yet, notwithstanding of all this, the ignition and explosion appear simultaneous. So we believe it to be with the *impressions on the senses; the sensation* they produce; and the *perception* which accompanies it. In the case of touch they are simultaneous; and they soon become so, or appear to be so, with regard to the other senses; for as soon as we have learned that they are excited by external causes, which no man can avoid learning, the *impression, sensation*, and *perception*, are produced at one and the same time.

Perhaps we have gone far enough on the subject of *ideas*, as our object is merely to give our readers some notion of the questions generally agitated by metaphysicians; and, as far as in our power, to furnish them with the materials for forming clear conceptions, and accurate opinions respecting them. We have dwelt the longer on the doctrine of Reid respecting ideas, as his writings form, in fact, a new æra in the philosophy of mind in this country; we mean Scotland, for his works seem to be very little valued, or known in the southern division of the island. Indeed we cannot help thinking it a matter of regret, that the fame of Reid is now almost absorbed in that of his pupil Dugald Stewart; not that we think this philosopher unworthy to occupy the very highest rank among ancient or modern pneumatologists; but we are persuaded he himself will regret, should even his own fame obscure that of his master, whose merits and achievements in mental philosophy he has blazoned with so much eloquence and affection.

With regard to Mr. Stewart himself, we have only to say, that we consider him as the most elegant and judicious philosophical critic at present in existence. His merits, as yet, appear chiefly in explaining and expanding the views of his master, in separating what is salutary in other systems, from what is trifling or noxious, and in inspiring a conviction that it is possible to render the philosophy of mind both interesting and useful. To this praise we venture to add, that, of all living authors, he is the most accurate and most elegant writer of the English language. Our subjects of regret with regard to him are, that he is either too timid or too indolent; for, just when he has brought us to the brink of an original discussion, to which his powers are adapted, he puts us off with the promise of a separate dissertation on the subject. If he lives to redeem all his pledges, he will have no reason to complain of the brevity of human life; and the world will have reason to be thankful for so many additional sources of enjoyment.

We commenced this article, with stating the advantages arising from the study of metaphysical science; and we suspect there will be some who will think that we have been undermining our own position, by detailing the jarring, inconsistent, and uncertain speculations of metaphysicians. But, in truth, the advantage of metaphysical studies appears, not so much in the adoption of any particular system, or in adherence to any particular master, as in the habit of accurate mental analysis, and in correct investigation into the origin of our feelings, sentiments, and opinions. No man who has not been accustomed to such investigations can ever attain to any thing like accuracy in moral or intellectual researches: he may, indeed, be highly useful both to himself and others, by adhering to the rules and maxims prescribed by superior wisdom; but he must be a stranger to those refined pleasures which arise from contemplating the beautiful adaptation of means to ends, by which the mind approaches, as it were, a step nearer to the Deity.

The metaphysician may go wrong in his researches; but he is like the adventurous mariner, who explores seas unknown, and at his own risk points out the rocks, shoals and quicksands, which might endanger future voyagers. Perhaps he enters what he may reckon a secure harbour, or settles on what he supposes a fertile island; but if he does not discover his mistake in time, others are taught by his fate to avoid the experiments which have misled him.

There is no more uncertainty in metaphysics than in any other subject which is not founded on necessary truths. The same uncertainty occurs in all discussions respecting politics and religion; not that these subjects have no certain foundation, but from the impossibility of defining, with perfect accuracy, the conceptions of the mind respecting them; from which result differences of opinion, and sometimes fierce contentions: when, perhaps, all the while both parties are perfectly right according to the conceptions which they have formed, and the meaning which they have attached to particular words. There is no uncertainty, then, in the principles of morals; the uncertainty arises wholly out of misunderstanding on the part of the disputants, who frequently find, after long and furious wrangling, that they have been fighting about a phantom, and that there is, in reality, no difference of opinion between them.

The superiority of the mathematical sciences has always been supposed to consist in the superior accuracy of the definitions; it might have been said, in their infallible certainty: for they are all necessary truths. It has been said that the certainty of geometry arises solely from this,—that the geometrician measures and calculates only the ideas of his own mind, which he determines and circumscribes according to his own pleasure.* We do not think this an accurate view of the subject. The mind, we conceive, is as much conversant with realities in geometry, as in any other science; and the definitions employed, so far from being arbitrary, are all founded on necessary truths.

M de Maupertuis has placed this subject in a very clear point of view in an Essay, (in the twelfth volume of the *Transactions of the Berlin Academy*,) entitled, *Examen philosophique de la preuve de l'existence de Dieu*, &c. He says, that number and extension are the subjects of rigid demonstration; not because the mind has the power of forming gratuitous definitions, but because there is in these sciences a principle of what he calls *Replicability;* that is, we can divide number and quantity into any portions; we can halve them, quarter them, or raise them to any power, and still they will preserve, in all their divisions or multiplications, definite and necessary proportions.† Hence, we can proceed with infallible certainty in all our researches concerning them; and our most complicated calculations may all be reduced at last to identical propositions, such as *two and two are equal to four; and four is equal to two and two;* or to the metaphysical axiom, Whatever is, is.

Nothing of this kind can take place in metaphysical science: our sensations may, indeed, be stronger or weaker; but we cannot increase or diminish them in definite proportions. We cannot divide a sensation into halves and quarters; nor indicate the square root of a conception. We cannot even ascertain, that any definition which we can give, can convey to the mind of another, an accurate idea of our own conceptions and sensations.

From these circumstances, we think it must appear, that though there must necessarily be much diversity of opinion in morals, metaphysics, and religion, yet there is no reason whatever to suspect that they have not as sure a foundation as the demonstrative sciences. Amidst all the diversity of sentiment which occurs, who can divest himself of the moral and religious feelings which grow up with him from his birth, and influence his happiness and his hopes? And is it not a proof that these feelings have a sure and immoveable basis, when they continue to maintain their influence in spite of the jarring opinions which prevail respecting them; and the dangerous and absurd conclusions which are sometimes founded upon them?

We have already noticed incidentally, some of the metaphysical arguments for the existence of a God; but as this is a subject of the greatest importance, and involving some fundamental metaphysical principles, we shall treat it a little more in detail.

As the belief in the being of a God is the most important principle which can enter the human mind, so there is none which can be established by such a variety of proofs. In attempting to discover new arguments, or to display superior ingenuity, there can be no doubt that too much stress has often been laid on circumstances which are doubtful or inconclusive. The marks of design, of wisdom, power, and goodness, displayed in the works of nature, are generally supposed to afford both the most obvious and the most satisfactory evidence of the existence of an infinite and eternal cause. The Sacred Scriptures often illustrate this subject in very beautiful and sublime language, not so much to produce the belief of a God, as to excite feelings of reverence and adoration at the contemplation of his works. Thus it is said, in the Psalms, that *the heavens declare the glory of God, and the firmament sheweth forth his handywork;* and the Apostle tells us, that *the invisible things of God are clearly seen, being understood by the things which are made.*

At the same time it must be confessed, that we are extremely apt to err in our speculations respecting final causes, and that the utmost caution is necessary in selecting instances, lest we fix on such as may be subject to challenge, and thus weaken an argument which, if judiciously managed, must be irresistible. We know no author who has handled this argument more successfully than Paley, in his *Natural Theology*, in which, from an examination of the various parts of the human frame, he has traced the clearest proofs of benevolence and wise design, and has shewn, at the same time, that any inconveniences or evils that may arise to the system are incidental, and form no part of the original plan.

We have no doubt, that the same reasoning is applicable in all the different departments of nature; though we are, in many instances, too ignorant to discover the wise adaptation of their several parts, and their mutual subserviency to promote the good of the general plan. We even see many things which puzzle and perplex us, and which we cannot reconcile with our limited views of expediency and wisdom. We may, for instance, admire the wisdom displayed in the structure of a snake, or a scorpion, or a poisonous plant, or venemous insect; but then we are led to inquire, "why all this apparatus, in the case of things which are positively hurtful?" We suspect that it is quite impossible to give any thing like a rational system of theology from the light of nature. But if we admit that man is a fallen and sinful creature, and obnoxious to punishment, we can perceive a reason why he should be subjected to such scourges. They remind him of his delinquency; and they teach him

* Si le geometre est moins sujet a broncher, que le philosophe, c'est uniquement parce qu'il ne mesure et ne calcule que des idees, les quelles il determine et circonscrit lui meme a sa phantasie. *Mem. sur appercep.* &c par M. Merian.

† He states also another reason for the superior clearness with which we discern mathematical truths. Our other perceptions are confined to one sense. The ear, the nose, the palate, &c. do not interfere with the provinces of each other; they have distinct perceptions appropriated to each. But the idea of number, and of *replicable* quantity, may enter the mind by each and all the senses. A being with only the sense of smell, would have the idea of number as soon as *two* different kinds of odours reached his nose: and so with the other senses.

caution, prudence, and preparation for death. Virgil, indeed, without the aids of which we speak, discovered a final cause for the existence of noxious animals, not very remote from that which we have suggested.

> Ille malum virus serpentibus addidit atris, &c.
> Ut varias usus meditando extunderet artes :
> Nec torpore gravi passus sua regna veterno.

The atheistical arguments, if arguments they can be called, are all extremely frivolous and absurd, equally destitute of foundation, either in metaphysics or in facts. Some of them are built on the apparent irregularity and want of benevolence, discernible in the arrangements of nature ; yet it is from the beautiful order and wise design manifest in all the parts of nature, which we have been enabled to examine, that the theist derives some of the most convincing evidences of a Supreme Creator and Governor of the universe. When we see, however, the two contending parties taking their stand on the same ground, and endeavouring to draw from the same source arguments to support their opposite systems, we may see the necessity of caution in selecting our instances, lest we fix on some point which may be untenable, or on some fact which may be imperfectly ascertained, or on some intention of the Author of nature of which we are not competent to judge.

But it is surely fair to conclude, that wisdom and benevolence prevail throughout the whole, since we have always discovered them in those parts which we have most thoroughly investigated, and that our ignorance of the uses and application of any of the objects of nature or arrangements of Providence, forms no ground whatever for arguing against them. Were this rule observed, atheism would be deprived of all its arguments drawn from the apparent imperfection and irregularity of the works of nature.

To obviate the arguments for the being of a God which Theists have drawn from the structure and preservation of animals, Atheists have alleged, that blind chance, or fate, or whatever else they may choose to call it, produced at first, an infinite number of animals of all possible natures, forms, and structures ; but that those only survived which *happened* to have the qualities and properties adapted for preservation. The animals without mouths, for instance, would soon perish ; those deprived of the organs of generation could not propagate, and wherever the structure necessary to the vital functions was imperfect, life would soon be extinguished ; the animals only which *happened* to be perfect could live and propagate. Atheism must be reduced to miserable shifts indeed, when it has been obliged to have recourse to such arguments. Perhaps they ought not to be answered in any other way, than by shewing that they are not only unfounded in fact, but directly opposed to every known fact in the constitution of nature. For where have we ever seen any instances of such promiscuous and casual productions ? Are there any who now believe in the production of animals by the solar heat acting on the slime of the Nile, independent of the usual process of generation ? If there are any such, they may be influenced by the atheistical hypothesis which we have stated ; but no man in his senses would attempt to argue with them, as they hold principles totally inconsistent with the known facts and analogy of nature.

But it may be demonstrated, on the soundest principles of metaphysics, that the hypothesis is absurd and impossible. For when did this *chance*, or fate, or whatever it was, begin to operate ? If it had a beginning, it must have had a cause : this is a metaphysical axiom ; and the man who denies it, is no more a subject of argument than he would be who should deny that two and two make four. If then, this *chance*, *fate*, &c. had a beginning, it cannot be the cause of any thing, since it is itself caused by something else.

But we are prepared to hear the Atheist affirm, that this principle of his is eternal, and had no beginning. On this supposition, then, it must eternally operate ; and what has been must always be, for to suppose any interruption in the continuity of eternity is absurd. But, according to the atheistical supposition, this eternal principle acted only once in a confused and random manner, and has ever since acted regularly and uniformly. Here, then, is an evident change, in an eternal, self-existent principle, which is also absurd ; for if change and chance be essential to it, they should operate always, which is not the case.

The philosophy of Epicurus is atheistical, though he himself, and many of his followers, admitted the existence of a God. But this was merely to save appearances, and to escape the inflictions of the law, which was particularly severe against Atheism in all the heathen states ; indeed, the prevailing error was quite of an opposite description, and ran into the extremes of Polytheism and Idolatry. This error, pernicious as it is, is, nevertheless, infinitely more excusable than Atheism : for Polytheism may easily arise out of wrong conceptions of the attributes of God, whilst Atheism can only spring out of the most criminal inattention to the evident displays of the divine power, goodness, and wisdom.

Epicurus and his followers, whilst they admitted a God, denied his providence, and endeavoured to shew how the world could be made without Him. This they achieved by the fortuitous concourse of atoms, which, moving from all eternity, were, at last, by some miraculous accident, jumbled into the present goodly order of things. (See Atomical Philosophy.) This hypothesis is too absurd to have any supporters in modern times, and yet it is as rational as any other system which excludes the agency of Deity in the formation and government of the universe.

Another Atheistical hypothesis is, that the present order of things is eternal, and that one thing has produced another in infinite succession. An infinite succession *a parte post*, might, in one sense, be admitted, for we can easily conceive an order established by the Almighty which shall never have an end. But an infinite succession *a parte ante*, is absurd, for it would imply that infinity is made up of finite parts, and that it may be increased or diminished, which is a contradiction. If the series of causes and effects was infinite a thousand years ago, it is more infinite now, for it has received numberless additions. Here, then, would be an infinity which is not yet infinite. Or, viewing it differently, if the infinite series was complete a thousand years ago, then, in that case, we have an infinity which is already terminated, which involves an absurdity.

But, leaving the absurdities and impieties of Atheism, let any man cast his eyes on the visible creation, and on the various objects of nature, and without entering into any speculations as to the uses and ends of particular parts, let him ask himself this plain question, " Whence arose this order of things?" To suppose them eternal, would be to make them self-existent, immutable, indestructible; in other words, it would be to suppose that they had a necessary existence, and that the very supposition of their destruction would involve an impossibility. But how ill do any of these attributes apply to any of the objects of the visible universe? Instead of being immutable, we see them every moment liable to change; instead of being indestructible, we have no difficulty in conceiving their utter annihilation: indeed, we cannot conceive how they should be kept from it, but by the sustaining influence of Him who created them, for God himself cannot make any thing independent of himself.

Whence, then, had the world its beginning? It could not exist without a cause; for this is the property of a self-existent and necessary being, which, as has already been seen, the world is not, neither could it be the cause of its own existence, for, in that case, it must have acted before it was, which is impossible. It must owe its existence, then, to a being, self-existent, uncreated, eternal: and this being we call God, who created all things by the word of his power, and who has informed us in the records of inspiration, that a time shall come when the elements shall melt with fervent heat, and all things shall be dissolved into their original non-entity, or moulded into new forms and modes of existence, by the *fiat* of the Almighty.

All the ancient philosophers held *creation*, in the sense in which it is now generally understood among Christians, to be impossible. It was an axiom with them, that *nothing can be produced out of nothing; nihil fit ex nihilo.* On this principle, all that they allowed to the agency of the Deity, was the arrangement of pre-existent materials, and the moulding of an external material substance into the form which it now exhibits in the visible universe. This is liable to all the objections which we have already stated. It gives to matter a necessary existence, and, of course, represents its destruction as impossible. The doctrine of Spinoza is the legitimate offspring of this axiom of the ancients. He saw, that to make matter eternal, was to invest it with the essential attributes of Deity; but, instead of being staggered by this consequence, he made it the foundation of his theological system; if that can be called theology which is founded on the motion of a material Deity. He held, that no being can communicate any thing but its own nature to another; taking it, therefore, for granted, that the material world exists, he thought that it followed, of course, that it must have proceeded from a material origin.

There cannot be a grosser mistake than to suppose, that the Supreme Being can be compared to any thing which we observe in the visible universe. Aristotle, though no great theologian, yet avoided such an unphilosophical notion as this. For, whilst he admitted that the Deity was the first mover of all things, he laid it down as an incontrovertible maxim that he himself was unmoved, *principii enim nulla est origo.* Instead of being essential to his nature to possess the qualities of any visible substance, his essence is to be conceived as directly opposite to every thing that is cognizable by our senses. Every object in nature may be increased or diminished, but God is infinite, and admits of neither increase nor diminution: every thing that we see is mutable, but *with God there is no variableness nor shadow of turning;* in short, his essential attributes cannot be imparted to any created being: the very idea of a *creature* excludes the possibility of such communication, for, if it is created, it cannot be self-existent and eternal. None of our faculties can enable us to form any thing like an adequate conception of the nature of God; nay, they necessarily lead us to form wrong conceptions of Him. We can judge of things only by comparison, by number, measure or weight. But to what shall we compare God? We may compare the flame of a candle to the light of the sun, or a grain of sand to the globe of the earth, or to the masses of matter which compose the heavenly bodies; for, however vast the difference may be, there must be definite proportions among all created things. But God is infinite, and cannot be compared with any object which we have ever seen, or with any standard which our minds have ever conceived. The only idea that we form of infinity is by adding continually, till the amount exceeds our powers of comprehension, and then we fancy that we have a conception of something which is infinite. But it is a contradiction in terms, as has already been shewn, to suppose an infinity constituted by the endless addition of finite parts.

This, however, we may know with certainty, that we daily see and feel the operations of an infinite eternal being, and this is sufficient for our purpose, and for inspiring confidence and hope, though the nature of God be unsearchable, and his ways past finding out. We imagine, indeed, that we can form some idea of the manner in which the Almighty actuates and pervades universal nature, by comparing it with the way in which the soul actuates the body, and communicates its influence to its various organs and members. This analogy or illustration has been employed in almost every country where any discussion has taken place respecting the nature and operations of the Supreme Being. Hence he was called the *anima mundi*, by the ancient philosophers; and the poets, taking up the same idea, represented all things as full of God. *Jovis omnia plena.*

It is perhaps a legitimate illustration to say, that as the soul actuates the body, so God actuates the frame of nature. But beyond this we cannot advance a step with safety; for we shall soon find that the comparison must utterly fail. Our souls and bodies are only a part of the general machinery of nature, (if we may use this expression,) put in motion and upheld by the hand of the eternal workman. We may, then, infer with infallible certainty, that he is wise, and powerful, and good; in the same manner as we can judge from effects, that these qualities may belong to human agents: but the motives which influence men to the practice of virtue can afford us no explanation of the counsels of God. He works in us to will and to do of his good pleasure; the motives which impel us to action are exceedingly various, and very often beyond our control: they are often entirely unforeseen; and the most important events in the history of our lives frequently arise out of circumstances unexpected, and apparently accidental. All this is entirely inapplicable to God. He acts of himself alone, and never can be influenced by external motives, since all things are ordered by him, and are dependent on him.

From what we have already said respecting the nature of God, we think it must follow by necessary consequence, that there can be but *one* God. One infinite being excludes the possibility of any other possessed of equal or independent power. Hence God, in order to give the Israelites the most impressive idea of the unity of his nature, made himself known to them by his attribute of *self-existence*. For when Moses asked his name, he commanded him to say to his countrymen, "*I am* hath sent me unto you."

As God is infinite, self-existent, and eternal, he is also unchangeable. Every change in any being is a proof of imperfection, even though the change should be for the better: for a being susceptible of improvement cannot be absolutely perfect. But *God is the same, and changeth not*. No addition can be made to his knowledge or happiness, he can therefore have no reason to wish to change: and as there is no power superior or equal to his own, there can be no necessity which can compel him to change. None of those circumstances which produce a change in human conduct can have the slightest influence with God. We are often compelled to change our purposes, because they have been planned in ignorance, and circumstances which we could not foresee have rendered them impracticable. The most pernicious of all absurdities would be laws and regulations which could not be altered. Such, we read, was the case with the laws of the ancient Medes and Persians; and the only consequence of such regulations must have been to obstruct the improvement of the human race in happiness and knowledge. But nothing can ever occur to induce God to alter his purposes; for they were not formed after the manner of the short-sighted plans of mortals. They are always founded at first in infinite wisdom, and with a perfect knowledge of every thing that is to come to pass, and therefore there can be no reason why they should ever be changed. When we see a nation at one time prosperous and successful, and at another discomfited and depressed, and when we ourselves experience alternate vicissitudes of gladness or sorrow, we must not suppose that these outward changes of fortune proceed from any change in the counsels of God. He has always the same object in view, viz. the happiness or improvement of men; and he adapts his dispensations to their circumstances, according as they need encouragement, correction, or assistance.

We have already alluded to the argument which Dr. Clarke employs to prove the existence of a God. It arose out of some sublime metaphysical ideas of Sir Isaac Newton, respecting the nature of the Supreme Being. He had said, *non est duratio et spatium, sed durat et adest*, &c. Dr. Clarke conceived, that in space and duration he had got hold of two qualities, which, as they could not belong to any created substance, must be attributes of the necessary self-existent being. We give the sum and substance of his doctrine in his own words. "The supposal of the existence of any thing whatever, necessarily includes a pre-supposition of the existence of space. Nothing can possibly be conceived to exist, without thereby pre-supposing space; which therefore I apprehend to be a property, or mode of the self-existent substance; and that, by being evidently necessary itself, it proves, that the substance of which it is a property must be also necessary."

We most willingly do justice to the many profound and enlightened views which occur in Dr. Clarke's *Demonstration of the Being and Attributes of God*: but we think his main argument rests on a false foundation. So far from space being necessary to the existence of every thing, mind, with its affections, has no relation to it: and, with the exception of the ideas which arise from touch, we might have had every other idea, feeling, and affection which can enter the human mind, without being so much as able to form an idea of space. Where was space when there was nothing else but the Deity? It was then a non-entity; and it is still so; never having had any actual existence; but possessing the *potentiality* of admitting the existence of every created thing. In short, space is a mere privation; and we might as well assign a real existence to silence, because it has the potentiality of admitting sound, or to darkness, which has the potentiality of receiving light, as ascribe reality to space, which has merely the capacity of admitting the existence of material substance. It has been said, that we cannot conceive the annihilation of space: annihilate matter, and we cannot conceive that space can have an existence. It exists only in our conceptions; and is as foreign to the nature of God, as the passions and feelings of men, which never can be predicated of the divine essence.

Mr. Locke says, that though a man were placed at the utmost conceivable verge of creation, yet he would still be able to thrust out his hand beyond himself: and hence he argues that space is infinite. It would be just as rational to say, that there are no limits to non-entity. God alone is infinite: and he has provided a theatre for the display of his infinite power; and to suppose any limits beyond which created substances could not exist, would be to limit the power of God.

We hope that we speak with sufficient reverence, when we say, that the infinite mind can have no idea of *time*, which arises solely from the succession of ideas in our own minds. No such succession can take place in the divine mind. With God, *a thousand years are as one day, and one day as a thousand years*. In the same manner, space has only a reference to our conceptions; and we view it as consisting of definite portions, added together without end. We can evidently divide it into parts; we can suppose any substance to be annihilated; and yet we can form a clear conception of the space which it occupied, and of the dimensions which this space possesses. But nothing which consists of definite parts and proportions can be a property of the Divine nature, which is without beginning, without end, and without limitation, infinite, immense, and omnipresent.

The moral arguments for the immortality of the soul will be found under the article *Moral Philosophy*. The metaphysical arguments for the soul's immortality are by no means so satisfactory as those which we have adduced to prove the existence of a God. The ancient metaphysicians generally admitted that the soul was immortal: but they inferred this from the doctrine of the soul's pre-existence, which was almost universally received among them. They saw, that if they admitted that the soul was created, they must instantly renounce the argument for its inherent immortality: for they held, that nothing which was created could lay claim to natural immortality. They supposed the soul to be an emanation from the Deity, or an excerpt from his substance, and that it would again be absorbed into his essence. This doctrine destroyed any profitable conclusions which might be deduced from the soul's immortality: for it went to annihilate personal identity, and virtually to set aside a state of punishment and reward. It was attended with other absurdities, which are thus stated by St. Augustine—

"Quid infelicius credi potest, quam Dei partem vapulare, cum puer vapulat? Jam vero partes Dei fieri lascivas, iniquas, impias, atque omnino damnabiles, quis ferre potest nisi qui prorsus insanit."

The only metaphysical argument, of any weight, for the immortality of the soul is, that as the soul cannot be affected by the vicissitudes which alter or decompose material substances, it can be destroyed only by annihilation: but we have never seen any thing like annihilation, even with regard to material substance—"Omnia mutantur, nihil interit:" of course we have much less reason to suspect the annihilation of the soul, which we have never seen subjected to any of the changes which produce such striking alterations in the appearance and qualities of matter.

But no doctrine is more completely established than the immortality of the soul, when we take into view the moral and religious arguments drawn from the capacities of the soul, and the general administration of God with regard to this lower world; and more especially when we attend to the instructions of that Divine Teacher *who has brought life and immortality to light*, and confirmed the doctrine by his own resurrection from the dead.

METASTASIO, Pietro Abate, the celebrated dramatist, was born at Rome on the 3d of January 1698.* His birth name was Trapassi. We shall immediately have occasion to mention the circumstance in consequence of which it was changed. His family had once been opulent, though reduced to poverty by gradual decline. His grandfather, Felician Trapassi, was one of the thirty inhabitants of Assisi, to whom the freedom of the city belonged. The father of the poet, Felici Trapassi, was however unable to subsist in his native place, and enlisted for a soldier in the regiment of Corsi. He soon afterwards married Francesca Galasti, of Bologna, by whom he had many children. The poet was their second son. Felice, whilst he was in garrison, added something to the scanty pay of a soldier towards the maintenance of a family, by becoming an amanuensis; and having fulfilled his military service, and by extreme industry and economy saved a little money, he entered into partnership with a shopkeeper at Rome, for the sale of goods which belong to what the Romans call l'arte bianca, consisting of oil, flour, pastry, and other culinary materials. Having prospered tolerably in this kind of merchandise, he placed his two eldest sons, Leopoldo and Pietro at a grammar school. Pietro (our subject) soon discovered an extraordinary quickness for learning, and a disposition for poetry. He could turn extempore verses on any given subject before he was ten years of age. This faculty he used to exercise after school hours at his father's shop, where crowds would assemble in the streets to hear the young improvisatori. During one of those tuneful fits, the learned civilian and critic, Gravina, accidentally passed, and was so struck by the harmony of the child's verses, and the sweetness of his voice, as well as by the liveliness of the thoughts which he threw out "*al improvista*," either on persons who stood near him, or any subject of their suggesting, that he stopt to admire him, and offered him money. The polite refusal of the little bard to accept of his donation increased his admiration of him—he resolved to adopt him, and went immediately to solicit the consent of his parents for that purpose. As the civilian did not propose to take him from Rome, his father saw no necessity for refusing the proffered patronage, and the next morning Pietro was consigned to Gravina's care, who gave him the Greek name of Metastasio, as *μεταστασις*, *mutatio*, seemed at once to express his former name of Trapassi, and his new situation as an adopted child.

It seems at first sight rather inconsistent, that his patron, who had adopted him on account of his poetry, should have destined him to a study so unpropitious to poetry as that of the law; but Gravina was himself a lawyer; and, excepting the church, there was no other profession by which emoluments and honours could be then attained. At first, Metastasio was set to the perusal of pandects, decrees, and edicts—he nevertheless read the poets, by Gravina's permission, particularly Ariosto and Homer; and having, at the age of fourteen, produced his tragedy of Giustino, an astonishing work for a boy, though Metastasio afterwards regretted its appearance among his riper works; his patron not only tolerated but encouraged his poetical bias. Gravina took him, when he was 18, to Naples, expressly to afford him an opportunity of singing extempore with the most celebrated improvisatori at that time in Italy. When he appeared in Naples, he soon became an universal favourite. Nothing was to be heard of but his beautiful extemporaneous verses, which his hearers carried away in their memory—the grace and dignity of his elocution—and the inspired expression of his countenance.

With his poetical pursuits, he still continued the study of the law; and in order to obtain a passport through the only other promising road to preferment at Rome, he took the minor orders of priesthood, by the advice of his affectionate master. At 20 years of age he lost his patron Gravina, who died, aged 54, leaving behind him the character of a moderate poet and orator, but of great learning and classical knowledge, and considerable acuteness in criticism, though not unblemished by asperity. He rendered his name more celebrated by protecting Metastasio than by all the works of his own pen. The benefit of his influence on Metastasio's taste has been doubted, for he was a precisian in his ideas of classical purity, and it is supposed that if he had lived, his advice might have cramped his pupil's genius with rules of Greek art, and implicit imitation. However this may be, Metastasio's expressions of grief for his loss, which were strongly conveyed in poetical effusions, were never suspected of being insincere, though his mourning for him was that of an heir, which is sometimes so ludicrously doubtful,—for Gravina, faithful to his promise of treating him as his own child, bequeathed to him 15,000 Roman crowns, an excellent library, rich furniture, and a small estate in the kingdom of Naples. The specie alone, (equal to between three and four thousand pounds,) was, according to the value of money in those days, a sufficient independence; but among the lessons which his patron had taught him, he seems to have forgotten those of worldly wisdom. His legacy was soon spent, not indeed in vicious courses, but in the munificence of good cheer which he shewed to the admirers of his poetry and the frequenters of his table. In two years

* Dr. Burney (life of Metastasio) says the 6th of January. We follow the date of the life prefixed to the Florentine edition of the poet's works.

only an insignificant landed property remained; but though his fall was like Timon's, he had nothing of the misanthrope in his bland and benevolent disposition. At two and twenty, he set himself to renew the study of the law as a profession; and, as if he had resolved to secure himself against the seduction of the muses, he placed himself under an advocate of the name of Paglietti, a man who is described as "all law," a bitter enemy to poetry—one who hated the sound of verse, and the very sight of a poet; and was mercilessly intolerant of the slightest deviation from worldly prudence. One may figure a whimsical scene, in conceiving the shrewd and suspicious lawyer receiving such a noviciate, a youth already known and celebrated for poetical genius, but, with his fortune spent, obliged to determine in earnest that he would prosecute his legal studies. The assiduity of Metastasio is said to have at first inspired Paglietti himself with confidence, that he was thoroughly weaned from poetry; and we are told, that many who had before admired his verses, now regarded the rapidity of his progress in legal knowledge with still greater astonishment; but this change was an effort against nature, and could not continue. At the end of a year, we find him making a sly breach of his contract with the rugged advocate, by writing an epithalamium of 100 octave stanzas, at the instigation of the Countess of Althau. Then came his drama of *Endymion*, under the same sedative influence. The viceroy of Naples next prevailed on him to write the drama of the *Garden of the Hesperides*, on a promise that it should be kept a profound secret from his inexorable lawyer. His next drama was *Angelica*, the plot of which is taken from Ariosto. The poems which he produced at Naples were universally admired, particularly the *Gardens of the Hesperides*, but none felt the beauties of that drama so forcibly as Signora Marianna Benti Bulgarini, commonly called the *Romanina*, the greatest female singer and actress of her time, who performed the part of Venus in that piece, and was so enchanted with the poetry, that she would not rest till she was introduced to the acquaintance of the author. She felt, on seeing him, (says his biographer), an uncommon regard for him, and it was believed to be mutual. Meanwhile his legal friend Paglietti did not regard him by any means with the same pleasant looks as the actress his admirer, the *Romanina*. His poetical reputation was now blazoned abroad; and his disgust at the law, added to the severity of the old advocate, soon became sufficiently strong to make him wish to abandon the profession. Meanwhile the Romanina pressed him to take up his residence under her roof, and her husband joined in the same request. Metastasio was not insensible to the apparent indecorum of quitting a grave profession, as well as of laying himself under obligations to the family of Bulgarini; but, after a struggle in his own mind, he gave way to his love of poetry and leisure, and possibly also to his partiality for the lady, and accepted the invitation. To this proceeding, whatever may be thought of his motives, the world was perhaps indebted for the direction of his exquisite genius into its proper channel.

At the request of the Romanina, he wrote his "*Didone Abbandonata*," which was perhaps the first perfect musical drama that ever graced the Italian stage. The Romanina was a great actress, and a good judge of dramatic poetry, and Metastasio was obliged to her for suggesting the finest situations in his *Didone*. She was thought, with the exception of Mingotti, to be the only instance ever known of a female singer who had studied stage effect as well as harmony, sufficiently to enlighten the author of the words which she sung, as well as the composer of the music. The celebrity of the *Didone* occasioned its being set by the best composers of the time, for the other principal theatres of Italy, and it brought the author a considerable pecuniary reward.

In 1727, the Romanina having fulfilled all her theatrical engagements at Naples, was ready to return to her native city of Rome, provided her beloved poet would accompany her. Metastasio hesitated for some time, but at length consented, on condition that, in return for the hospitality which he had received under her roof at Naples, she and her family would consent to be his guests at Rome, where the relatives of Metastasio still resided. He therefore wrote to his agents to procure a house for the reception of his two families of the Trapassi and Bulgarini; and from the time of his arrival in that city, till his departure for Germany, they all lived under the same roof. The Romanina, as more accustomed to the superintendance of a family, managed the household; the rest attended to their own pursuits; while Metastasio received his visitors, wrote his verses, and increased his celibrity.

He finished several operas during his residence at Rome, as the "*Catone in Utica*," Egio, Semiramide Reconnosciuta, Artaserse and Alessandro nelle Indie, and his reputation continued to increase, not only in Italy, but spread beyond the Alps. But with all the praises which he acquired, it does not appear that he reaped much profit from his labours; and though he could not be said to be in necessitous circumstances, with his generous friend's purse at his command, he was poor, and surrounded by barren prospects compared with the claims which he had upon the gratitude of his country, as the restorer of her poetry, and as the greatest living ornament of her language. He had invited the Romanina to be his guest, but was obliged to be indebted to her liberality. She tried to console him with the most affectionate appeals to his fortitude, but his spirit, though naturally cheerful, began to sink into gloom and despondency. His affairs were in this unpromising state, when, in 1729, he received an invitation from the Court of Vienna to come and reside there as coadjutor to Apostolo Zeno, the imperial laureate. His pension was to be three thousand florins (L.300) a year. The offer was the more flattering, that it came in consequence of the recommendation of Zeno himself, who had enjoyed the laurel since the year 1718. His chief employment had been to furnish lyrical dramas for the imperial theatre, and they were reckoned the best dramas of the kind which the Italian language could boast of, before those of Metastasio. Zeno, declining in health and years, most honourably recommended a substitute for himself in this employment, who, he must have clearly foreseen, would eclipse his own poetical memory.

On quitting Rome for the imperial capital, Metastasio consigned the care of all his effects and concerns to his zealous friend the Romanina, who willingly took charge of his little places, and of the sums of money which he left behind him for the support of his father. He arrived in Vienna the 30th of July, 1730. The first regular opera which he produced for the imperial theatre was "Adriano in Siria," which was set to music by Caldara. Of its success we have no account; but we may conjecture that it was well received, from the favour which was shown to it by the rest of Europe. In one of his letters to Marianna Bulgarini, he gives a pleasing account of the reception of "Demetrio," the second opera which he composed in Vienna. The applause, he says, was such as the oldest people never remembered having been given to any theatrical piece. The audience repeated parts of it in conversation as if it had been German. He had not only been successful, but had conquered the envy attending on success; and "those," he says, "who were before his enemies, are now become his apostles." His correspondence with Romanina continued to detail to her the successive reception of his pieces, and the other incidents of his life, till no great time before her death, which took place in 1734. She manifested her attachment by beqeathing to him all her possessions after the decease of her husband, to the amount of 25 000 crowns; but Metastasio, with much rectitude and propriety, declined the bequest. Inconsistent as it may seem with our ideas of law and decorum, the legality of this will is not questioned by any of his Italian biographers; and his renunciation of it is spoken of by them all as a most disinterested sacrifice. Of the nature of his connection with the Romanina, it is no great breach of charity to judge, that it was not probably quite platonic. The circumstance of her husband residing in the same house with them, both at Naples and Rome, might be thought indications of conjugal fidelity; but a chaste actress and opera singer is a still more uncommon phenomenon in Italy than in England. The female Italian opera singers, as Dr. Burney observes, generally find it convenient to have a nominal husband, who will fight their battles, and contend with the impressario, or manager of the opera. In the course of their correspondence, it appears as if the Romanina was at one time anxious to go to Vienna as a singer, and suspected Metastasio of not speaking openly on the subject. It was thought that he was fearful of the effect which her arrival might have had on his own reputation, as the Emperor Charles VI. was a prince of very rigid ideas of decorum. Yet, after all, it is not easy to part, on very harsh terms, with the name and memory of the woman who solaced the heart, and cherished the genius of Metastasio. Something may be allowed for the general manners of her country and her vocation. She was no ordinary person; she made no vulgar choice in her affection; and was neither mercenary nor inconstant in preserving it. The age at which she died is not precisely known; but she was probably older than Metastasio, having attained to the zenith of her reputation as a singer in Genoa in 1712. Metastasio speaks with deep grief for her death to those with whom it was not his interest to be ostentatious of such feelings. In a letter to his brother, he says—"Poor Marianna will never return; and I believe that the rest of my life will be insipid and sorrowful." It has been already noticed, that in early life he took the minor orders of priesthood. In one of his letters to his female friend, he mentions the death of a certain abate in Sicily, to whose vacant abbey he would have wished to succeed; but did not know in what diocese it was situated, or whether it was requisite that the candidate should be a regular ecclesiastic. It appears from other letters, that although he wished for secular perferment in the church, he had no intention to be an ecclesiastic "*in sacris*."

His course of life after his removal to Vienna, was little varied by other events than the successive production of his operas. In 1738, he was, without solicitation on his part, complimented by the city of Asisi with a patent of nobility. His appointment of laureate, and the profits of his compositions, enabled him to support a respectable appearance in society, and to live with all the comforts necessary to his retired and moderate habits. It may be suspected, however, that he was obliged, for many years, to cherish retired and moderate habits from necessity as much as choice; nor does he write to his friends at all times with unqualified satisfaction about his pecuniary affairs. "Charles VI.," he says in a letter to a friend, "as a reward for my long services, and to make up for my unpaid salary, granted me a thousand crowns in Sicily on a bishoprick or benefice in that kingdom; but all the bishops, abbots, and beneficed clergy became from that time immortal, and the kingdom was lost before I had received a penny The treasurership of Cosenza in Calabria becoming vacant, my august patron, remembering my unpaid arrears, destined it for me. I took possession—spent more than 800 ducats of my own money in fees and other expences; but before I had begun to to reap the first crop, the Spaniards entered the kingdom, and I remained with my patent in my hand, ready for curling my hair, or folding up sugar plums."

The Empress Queen, he farther relates to his correspondent, impoverished by a seven years' war, was obliged to diminish the salaries of her servants. To console him for this diminution, and for his other losses, she assigned him 1500 florins in Milan; but at the end of five years the promise was unfulfilled; and after fifteen years service he found himself in a worse state than when he had left his native country. This was undoubtedly a faithful picture of his affairs at one period of his residence in Germany. It is clear, however, that he must have ultimately saved money at Vienna in the course of his long life, from the sums which he left at his death.

These particulars of his private history are contained in his correspondence with the celebrated singer Farinelli. A friendship subsisted between our poet and that musician for fifty years, after they were separated and established in the service of different monarchs in the two most remote capitals of Europe. The poet and musician were nearly of the same age, and began their public career in the city of Naples at the same time. They regarded each other as twins of public favour, brought to light at the same birth, and united in one common interest. Metastasio never imagined his poetry injured by Farinelli's too florid style of singing; and such was his fraternal affection for his "*caro gemello*," that he overlooked or forgot the want of simplicity, action, and pathos in his singing so entirely, as to censure young performers for these defects in his letters to Farinelli.*

* Farinelli (whose voice was found to operate on the disordered mind of Philip V. like the harp of David on the evil spirit of Saul,) was retained in the service of the Spanish court with a pension of 300*l.* a-year, which, after Philip V. died, was continued under his successor.

The tenor of his life was uniform and placid at Vienna, if not remarkably happy; and whatever disturbance the absence and remembrance of Marianna may have given him, he never seems to have fallen again in love. "You believe me," he says in one of his letters to a friend, "in danger here from the charms of some tranquil Teutonic beauty; how mistaken you are. Here, love and hatred never disturb the sleep of any mortal: here the body cares very little for the affairs of the mind; at night you may be a favourite, and in the morning unknown. Eagerness, agitation, solicitude, little quarrels, reconciliations, gratitude, vengeance, &c. all that gives terror or pleasure in the commerce of delicate souls, is here thought ridiculous, or fit only for the embellishments of romances. It is incredible to what a pitch of indolence the placid nymphs of this place are arrived. I should despair of finding one that would relinquish a game at piquet for the loss or death of her dearest lover. There are many who would think the turning aside from their sampler among the most mysterious excesses of genius." He divided his apartments with the family of Signor Martinez, the imperial librarian, whose sister, brought up from the cradle by the poet, and highly accomplished in literature as well as in music, devoted herself with filial attachment to his amusement. From the period of his fixing in this intimacy with the family of Martinez, he acquired a habit of dividing his time so regularly, that a single day became something like a miniature of his life; and he was often in jest, though with great justice, compared to a clock. In the morning he went always at the same hour to hear mass at the church of the Capuchins; from thence he went to visit the Countess of Althau, with whom, his Italian biographer says, that he regularly spent his time from eleven till two in the morning, and from eight till ten in the evening; and after her death he spent the same allotted hours with his friend Perlas, the canon of Breslaw. We must suppose that he met at that lady's house the circle of friends to whose society he was chiefly attached. He rose, took his meals, and went to bed always at a stated hour. At six in the evening he received at home the Sardinian minister and Baron Hagen, the president of the imperial Aulic council. With these friends, he spent his time till eight, usually reading the Greek and Latin classics in chronological order. In the intervals of the day he wrote his verses and his letters. When he had finished his writing, he never left a scrap of paper on the table. He was in short such a lover of order in all his ways, that he used to say jocularly that he feared Hell chiefly besause it was a place of utter disorder, and because he understood that in the infernal regions "nullus ordo sed sempeternes horror inhabitat." He was accused of bring finical in his person, from his attachment to odoriferous washes, and delicate soaps and pomatums. In his dress he was excessively neat and simple. He had a frailty in his advanced years of being averse to declare his age, and was not fond of alluding to his humble parentage. Having never had the small-pox, he could not bear to hear the word mentioned; and when Lewis XV. died of that distemper, not only that circumstance, but even every thing concerning the Court of France, were forbidden topics in his presence. This weakness was the result of the uncommon dread of death, with which he was so tormented, that when any of his friends were given over, he never inquired more about them, nor was willing to hear their names mentioned. These were foibles in a character upon the whole highly estimable; for if not possessed of the strong and active virtues, he was perfectly free from jealousy, envy, malignity, and the selfish passions. In the April of 1782, having attained his 84th year, he was suddenly seized with a fever, which for some time made him delirious; but on recovering his senses he received the sacrament with symptoms of devout sensibility, which drew tears from the surrounding spectators; he also had the Apostolic benediction pronounced upon him in the article of death. This benediction was sent to him from Pope Pius VI., who was then at Vienna, by the Nuncio Garampi. He was buried with great funeral solemnity by his principal heir, Signor Joseph Martinez, to whom he left his house and library, and about 100,000 florins. A remaining, though small portion of his fortune, went to his sisters.

Metastasio was of middle stature, rather inclined to be large, but well proportioned in his person, with fine dark eyes, an aquiline nose, a well-shaped mouth, and fresh complexion; and, even at his advanced age, never wore glasses. Dr. Burney found him, at 72, looking like a man of 50, and the handsomest person for his age he had ever seen. On his features, he says, was painted all the genius, goodness, and propriety, which characterise his writings. He was cautious and modest in his intercourse, and so polite that he was seldom known to contradict any body in conversation.

Our limits necessarily oblige us to give a general character, and not an analysis, of the works of Metastasio. They contain, besides his poetry, a number of letters to friends, which were published after his death, and some reflections on the poetics of Aristotle. Gravina had taken care that he should be a good classical scholar, and he had studied with some depth the principles of his own art. He has left also some poetical versions from Horace and Juvenal. He composed eight-and-twenty regular operas, without reckoning a number of short pieces and entertainments, containing both airs and recitatives, like his greater operas, and often animated with theatrical action. His subjects are taken indifferently from mythology and history; and deal not only with antiquity, but, in one instance, with the middle ages, in the romantic and chivalrous piece of Rogero. This grand variety of ages, and countries, and manners, not only gives much scope for theatrical decoration in the representation of his pieces, but prompts the reader's imagination, even without witnessing their exhibition, to form rich and numerous conceptions of scenery and spectacle, and furnishes the poet's own fancy with a wealth of local imagery. With all this wide field of subjects, however, Metastasio is far from exhibiting a fertile diversity of human characters, interests, and passions; nor has he even attempted to be a great painter of nature and history. The cause of this deficiency may have partly lain in the frame of his genius, and partly in the nature of the opera, to which the temperament of his genius, by long habit, conformed itself. His soul, as a poet, was, no doubt, fraught with impassioned feelings, and with high forms and conceptions of the sublime and beautiful; but he had not, perhaps, from nature, a profound or daring character of thought; or, at all events, if he had it, he could not exercise it in the soft, voluptuous, and abstracted reveries of the opera. He devoted himself to the musical drama with an exquisite feeling of music; and, where poetry is incorporated with music, however enchanting their united effect may be, something of the independent and excursive vigour of the latter will necessarily be sacrificed. The enchantment which we experience from hearing some noble war-song, or affecting strain of tender passion, powerfully sung, may seem for a moment to throw a doubt upon this truth. We are apt to feel, in such instances, that poetry and music are natural, and ought to be inseparable allies. And we are right in thus appreciating the magic reciprocity which is here exchanged between the two sister arts, when it extends no farther than to a simple burst of feeling, or the recitation of a short and simple story; for music can express passion, and powerfully aid the verbal expression of passion. But when poetry extends to the unfolding of complicated situations, to dialogue, and diversified descriptions of life, it leaves the expressive powers of music behind it; and if it accommodates itself to musical expression, it must lose by the accommodation. Music cannot paint manners, but would degenerate to burlesque and mimicry, if it attempted to do so. The opera poet, therefore, whose aim is to give his poetry that mould alone to which musical expression can cling, and that beauty alone which music can heighten and adorn, though he may bring the passions into play, and though he may be rich, ideal, and persuasive, cannot carry into imitation that boldness and truth, which make the drama "*hold up, as it were, a mirror to nature.*"

Metastasio, the finest genius who ever attempted the musical drama, illustrates this theory in his whole theatre. His characters are all general and abstracted representations of human nature. They have individual names, but not individual natures; they burn with passion; they are exalted by virtue or debased by vice; but are monotonously good or bad, without the particular and minute traits which make the pictures of human beings illusive semblances of reality. The hero of one age and country is exactly the same with the hero of another. They are virtues and vices personified, and in the extreme; they are defective in physiognomy. Yet, if we weigh Metastasio, not by his generic but specific worth in the drama, as a writer of operas, and not of tragedies, we shall find room for almost unqualified admiration. His operas are, on the whole, in so far exquisite dramas, that the story which they tell is managed with classical and skilful arrangement; their plots are striking, interesting, and well adjusted; the story is irresistibly captivating, fraught with grandeur and fire, as well as tenderness of passion. Love, loyalty, and patriotism, are eloquently expressed; and the harmony and diction, both of air and recitative, are supported with exquisite power and simplicity. His language is so perspicuous as to be almost as intelligible to foreigners as prose itself. His nine dramas the most esteemed, are those which he composed during the ten first years of his residence at Vienna. Issipile, Olimpiade, Demophoonte, Laclemenza di Tito, Achille in Teiro, Semirami de Riconosciuto, Temistocle, Zenobia, and Regolo. In our own opinion, the tenderness and luxuriance of feeling in Demetrio is equal to any thing in his works, and almost unrivalled in the drama. The third scene of the third act of Demetrio is peculiarly touching, where Cleonice, the princess of Egypt, who had been induced, by a false sense of honour, to give up her lover Alcestes, when repentance seizes her, when she finds herself unable to support a longer struggle against affection, and overtakes Alcestes on the sea-shore, in the moment of his embarkation. The eloquence of love was never more romantic and beautiful, than in her speech in that scene which begins—

> "*Nil tuo povero albergo*
> *Qu'ella pace godio, che in regio tetto*
> *Lunge de te quisto mio cor non gode.*"

Metastasio is eminently the poet of love, and, in general, very happy in delineating noble and amiable sentiments. It is astonishing how much *naive*, and simple feeling, and natural language, he has thrown into the most artificial department of the drama; with how little constraint he moves in lyrical poetry, and with what artless, unaffected language, he unites the richest ornaments of imagination. In the opera, he is a poet without models, and without rivals. (*n*)

METELIN, anciently Mytelene and Lesbos, an island in the Mediterranean, at the mouth of the Gulf of Adramyti, on the south-west coast of Asia Minor.

This island is of a triangular figure: its precise dimensions are not ascertained; but in so far as we can collect, it seems about 42 miles in extreme length from north-west to south-east, 26 in extreme breadth, and the superfices probably may be computed at 500 square miles. Several rocky flats environing it are conjectured to have been once an integral part of Metelin, and some have supposed that an ancient concussion of nature rent the island itself from the neighbouring continent. The intermediate channels between two sides of it and the Asiatic coast, are nine or ten miles wide, with 50 or 60 fathoms of water.

There are no rivers here, but mountain torrents from the rains; numerous fountains, and many hot springs of different qualities, to which valetudinarians resort at all seasons, both for drinking and bathing. The southern coast is penetrated by two canals, each terminating in a spacious basin, forming two excellent and secure harbours, which are separated by the lofty Mount Olympus. Of these Port Caloni is the larger, but not so much frequented as the other Port Hiero, or Olisiere, lying towards the south-east extremity of the island. Traders repair hither during the whole year for cargoes of oil, and foreign navigators take shelter in it when adverse winds oppose their access to the Gulf of Smyrna.

The face of Metelin is mountainous: one chain of hills traverses the island in a longitudinal direction, and is intersected by another. Volcanic and calcareous productions abound. Granitic rocks on each side of the two channels, dividing it from the continent, are cemented by a calcareous substance; and among the petrifactions which occur at Port Sigri, the western extremity, are entire trunks of trees. Some parts of the surface of the earth are covered with a hard shining stony incrustation.

The climate is very fine; it rarely freezes during winter, and the summer heats are tempered by breezes from the sea. The island, nevertheless, is exposed to sudden storms from the Asiatic mountains, and towards the south coast it is insalubrious. Great mortality prevails in certain seasons; and whole villages are said to be occupied by leprous persons. Hippocrates celebrates the beneficial effects of the Lesbian climate on the body, and Demetrius Phalerius conceives that it invigorates the mind.

The ground is clothed with perpetual verdure, and the most luxuriant vegetation: almost all the mountains are well wooded, and exhibit a great variety of plants. Vineyards hang on the declivities of the hills, for the soil is friendly to the vine; and extensive plantations of olives afford an abundant produce. The ancients celebrated the quality of the Lesbian wine, but at present it is both rare and inferior, partly from the unskilfulness of the inhabitants, and partly because the grapes are converted to raisins, and also employed by the Greeks for making brandy. Neither the grain nor live stock are in sufficient quantity for home consumption. Horace speaks of Lesbian flour whiter than snow; and wool was formerly an article of export. The chief products, natural and artificial, of the present day, are about 50 000 or 60,000 quintals of olive oil yearly, most of which is carried to Constantinople; wood for shipbuilding, and pitch extracted from pines, for the same purpose. Nothing but pine is said to be used in the construction of the vessels, which are very light, and last ten or twelve years. Pococke mentions a manufacture of stuffs made of silk and flax, at a place called Peribole.

Considerable trade was carried on with France formerly: the French had a consul, and the English a vice-consul: but the former seems to have been withdrawn when it was ascertained that the oil of the Morea and of Candia could be obtained at a cheaper rate.

It is computed that Metelin contains about 40,000 inhabitants, consisting of Turks and Greeks in equal proportions, and a few Jewish families. The women are very handsome, with fine large expressive eyes and a beautiful complexion, which, however, they disfigure with paint; and they shave off part of the eye-brow, replacing it by an artificial one, connecting the remainder with the hair at each temple. The ancient Lesbian females are said to have had a public competition for the palm of beauty, which was adjudged by young men in the fane of Juno. But such contests do not seem to have been favourable to morals, as the people were considered dissolute: and a traveller of the last century remarks, that "the women have no better character for their chastity, nor the men for their sobriety, than in former times." In manners the modern females are rather masculine; they do not shun the gaze of strangers; they enjoy an uncommon portion of liberty, and even assume a paramount authority in all domestic arrangements.

Until lately, a remarkable deviation from the common customs of mankind prevailed regarding the law of succession here. The eldest daughter inherited the whole fortune of the family, while all the other children, male and female, were left entirely destitute. If there were only two daughters, the younger obtained no succession; and when the elder married, she remained in a state of subservience to her, wearing a particular habit, and attending her as a domestic. If the family consisted of more than two, this became the lot of the immediate younger daughter always, as her immediate elder sister married. Farther, it appears that the whole family possessions were transferred to the eldest daughter on her marriage, whereby she and her husband were kept in affluence, and her parents were reduced to an indigent condition, "and we ourselves," says the Earl of Charlemont, "have frequently been shown the eldest daughter parading through the town in the greatest splendour, while her mother and sister followed her as servants, and made a melancholy part of the attendant train." Something similar may be traced among various ancient countries; and there are some even now, where the birth of a son deprives the father of his public functions. In Metelin, a modification of the usage alluded to has been recently effected by the intervention of the Patriarch of Constantinople, together with the bishops and clergy of the island. Certain rights of primogeniture are preserved, by which the eldest daughter receives a third of the inheritance, the second a third of what remains, and the younger successively a third of the residue. Thus the immediate younger daughter, whatever be the number of the family, always receives a third of the remainder, after those before her have drawn their proportion.

The principal town, which is called Metelin or Castro, is situated on the east coast, where two harbours are formed by a mole of ancient construction. It is protected by a castle about three quarters of a mile in compass, consisting of two divisions of lofty embattled walls, each having its own governor and garrison, and these fortifications are defended by five or six hundred janizaries, most of whom are domesticated there. The population of the town amounts to two or three thousand Turks, three or four thousand Greeks, and thirty or forty Jewish families. It is a Bishop's See. Metelin covers part of the ground occupied by the ancient city. Molivo stands on the north coast, on the site of the ancient Methymnee, extending up the side of a hill, crowned by a spacious castle. It is about a mile in circuit, and contains about two or three thousand Turkish and Greek inhabitants; the latter have three churches and a bishop. The natives of this place are said to be distinguished as of old by a taste for music. Besides these, which are the principal places of the island, there are several villages, such as Petra, Akerona, Eresso, chiefly of small extent. Petra, or Porto Petra, on the west coast, is so named, from a high rock in the centre, which is accessible only from the north, and is surrounded on the top by a wall, whither the most valuable property is deposited by the inhabitants when alarmed for the depredations of Corsairs. At Akerona, on the north of Port Caloni, there is a desolate monastery, dedicated to St. John the Baptist. Eresso stands a little to the south of Cape Sigri in the neighbourhood of Ruins, denoting the situation of the ancient city of the same name. The houses in Metelin are constructed after a peculiar fashion, consisting of a square tower of hewn stone, raised so high as to overtop the trees, and command a view of the sea and the neighbouring island. The lower story is reserved for stores and granaries; and at the top are the apartments for the family, which are gained by a stair, chiefly built on the outside, and surrounding the tower.

Many celebrated men owe their birth to this island, among whom, perhaps, Theophrastus was the most distinguished, from having been a disciple of Plato, from Aristotle designing him for his successor, and also for the incredible number of his works. Pittacus, esteemed by the Greeks as one of their sages, was born in Lesbos, as also Alcæus and Sappho. In modern times, the two brothers named Barbarossa, the sons of a potter, who successively attained the rank of Dey of Algiers about the middle of the sixteenth century, owe their birth to this island.

Lesbos was one of the most famous islands of antiquity, but almost the whole remains of its grandeur are totally obliterated. Nothing but the faintest traces can be discovered of some of the eight cities which

Ptolemy says it contained. Four or five miles north-west of the town of Metelin are the ruins of a fine aqueduct, which has consisted originally of two arcades of grey marble surmounted by a kind of brick. In other places are seen the foundations of ancient castles and subterraneous cisterns. A white marble chair, of the age of Tiberius, which long attracted the notice of travellers, we have understood, has been lately acquired by a Scottish nobleman distinguished by his taste for Grecian antiquities.

Metelin has often changed its name. According to Diodorus it was called Issa; and after being occupied by seven generations of men, it was submerged by a flood, separating it from the continent, and destroying the whole inhabitants. Having regained sufficient fertility after subsidence of the waters, it was repeopled at a period which some conjecture to have been 1734, and others 1540 years anterior to the Christian æra. This island was often the theatre of warlike contentions during the subsistence of the Grecian States, and the influence of other nations in the Mediterranean. Under the name of Lesbos it became tributary to the Athenians, and afterwards formed part of the Roman Empire. It is uncertain when this appellation was changed; but Eustathius, who flourished in the twelfth century, mentions that it had been lately called Mytelene, as it was anciently denominated Lesbos. The Emperor John Paleologus ceded it to Gatilusio, a Venetian nobleman, under whose family it remained until besieged by Mahomet, who met with a determined resistance from the inhabitants. But their commander treacherously opened the gates of the town to the enemy in 1462, on a promise of being rewarded with the sovereignty of the Island. However, Mahomet, equally treacherous, put him to death when his services proved no longer useful. See Diodorus Siculus, *lib. iv.* § 81. Dallaway's *Constantinople, Ancient and Modern, p.* 312. METEORIC STONE. }
METEOROLITE. } See METEORITE.

METEORITE.

THIS term, derived from the Greek Μετεωρα, is here preferably adopted, as the shortest and most convenient appellation of a stony or metallic substance, which falls from the air, and whose descent is, generally, preceded or accompanied by a fiery meteor.

That stony, and even metalline bodies, have repeatedly impinged upon the earth's surface, and from great elevations, is a physical position from which no considerate and candid logician can any longer withhold his assent. The object of the ensuing pages, therefore, is not so much to prove the reality of such a phenomenon, as to supply our readers with a summary, but continuous review of its history, or, in other words, with a transcript of its modifications, and of the leading observations and reasonings to which it has given rise, thus approximating the results of various and dispersed documents, and reducing within a desirable compass the groundwork of future inquiry and discussion. We may, at the same time, confidently venture to indulge the reasonable expectation, that our exposition of facts and observations will suffice to convince those who have not heretofore examined the nature of the evidence on which it rests, that the phenomenon in question is neither doubtful nor chimerical, but entitled to all the credibility which can attach to human testimony.

In our present state of knowledge, we can feel no hesitation in ascribing a meteoric origin to certain detached masses of native iron, not merely because tradition accords with our opinion, but principally because the circumstance of their fall has been, in one instance at least, duly authenticated, and because their chemical constitution is, in some important particulars, analogous to that of undoubted meteorites. According to the discoveries of Proust and Klaproth, for example, native iron, reputed meteoric, differs from that which occurs in a fossil state, by the presence of nickel. Of the two pieces of Siberian iron in the Grevillian collection, one exhibits a cellular and ramified texture, analogous to that of some very light and porous volcanic slags. An attentive examination, moreover, reveals impressions or cavities of greater or less depth, and in some of which there remains a transparent substance, of a yellowish-green hue. The iron itself is very malleable, and may be cut with a knife, or flattened under the hammer. The other specimen is more solid and compact, but so blended and incorporated with the yellowish-green matter, that if the whole of the latter were subtracted, the remainder would consist of iron in the metallic state, and would present the same cellular appearance as the preceding. The stony portions of the composition usually assume the form of small nodules, generally of an irregular outline, but sometimes nearly globular, with a smooth, shining, and vitreous surface, and, both in aspect and properties, approaching to olivine. "I cannot help observing," says the Count de Bournon, "that there appears to exist a very interesting analogy between these transparent nodules and the globules I described as making part of the stones said to have fallen on the earth." The native iron from Bohemia, like the larger specimen from Siberia, is compact, and contains nodules, but not so numerous. They are, besides, quite opaque, and very much resemble the globules in atmospheric stones. This iron contains nearly 5 *per cent.* of nickel; and between 5 and 6 *per cent.* of the same metal seems to exist in a piece of native iron, brought from Senegal.

In like manner, we shall offer no apology for including in our chronological recital the mention of pulverulent or coloured showers, since the products of some of them seem to indicate a similar origin, and since, in several instances, their fall has even accompanied that of concrete masses. The colouring matter of alleged showers, however, has sometimes been found to be of a vegetable or animal nature, so that cases of this description are to be admitted with caution. Thus, the crimson snow, described by Captain Ross, in his account of his recent voyage to Baffin's Bay, is supposed by Dr. Wollaston to owe its complexion to some vegetable production, and Mr. Bauer fancies that he has detected in it the existence of a non-descript *Uredo*, which he, very appropriately, designates *nivalis*. With the exception of such instances, however, the black and reddish dusts, to which we shall have occasion to refer, may, perhaps, be regarded as replacing the grey and earthly portions of the friable meteoric stones. Nor is it improbable that the vitreous matter which accompanies the masses of native iron, may be the same portions completely fused, and that the dusts, meteorites, and ferruginous masses may have undergone different degrees of heat, which would account for their different modifications and appearances. Certain it is, that even sand was mingled in the Siena shower of stones, thus pointing to an intimate connection between silex in the loose and in the consolidated state, and thus justifying our insertion of the few examples of atmospheric sand that have come within our knowledge.

It may, moreover, be proper to premise, that although we have adopted Dr. Chladni's revised catalogue of meteoric appearances, and an article inserted in the second number of the Edinburgh Philosophical Journal, as the basis of our historical recapitulation of recorded cases, we by no means wish it to be understood, that we vouch for the truth of them all indiscriminately; for some of them rest on very slender or doubtful evidence; and a few we have purposely discarded, because we have been apprised, on unquestionable authority, that they were apocryphal. We may, however, pretty fairly presume, that the number of genuine occurrences of the phenomenon is, at least, not inferior to that which we purpose to quote; for it is reasonable to infer, that while the learned continued incredulous, even true reports might be rejected as fabulous; and several foreign collections of fossils contain specimens of reputed atmospheric origin, and exhibiting the features of meteoric physiognomy. It is, likewise, worthy of remark, that many fragments of *heavenly descent* may, at this moment, lie scattered on the earth, because, if abandoned but for a short time to the variations of humidity and temperature, to which the surface of our planet is constantly exposed, their metallic portions would be as speedily oxidized and degraded as a bit of polished steel, and thus render them to the eye of casual observation undistinguishable from morsels of those ferruginous stones which may be met with in almost every region of the globe. Besides, many relations of the phenomenon may have sunk into oblivion from the waste of time, or the stroke of calamity; and, on a fair computation of chances, meteors may have frequently exploded over desert tracts of land, or the pathless expanse of the waters.

From the sacred Scriptures of the Old Testament, we are not aware that any passage can be cited in direct proof of the descent of stones from the atmosphere. The ingenious but fanciful *Mr. Edward King*, indeed, in his "Remarks concerning stones said to have fallen from the clouds, both in these days and in ancient times," points to two passages as announcing such an event. The first occurs in the 13th verse of the 18th Psalm—*The Lord also thundered out of heaven, and the Highest gave his thunder: hail-stones and* COALS OF FIRE. This last expression has, no doubt, been conjectured to denote real hard bodies in a state of ignition: and the term *ανθρακες*, employed by the cautious Seventy, rather favours such an interpretation. The same expression, however, occurs in the verse immediately preceding, without admitting of this signification; and the phrase seems to be only a figurative mode of painting lightning; for, even in the sedate latitudes of the north, and in plain colloquial discourse, we currently talk of *balls of fire*, and *thunderbolts*, without any reference to solid matter. The other passage adduced by Mr. King, is the 11th verse of the 10th chapter of Joshua. *And it came to pass, as they fled from before Israel, and were in the going down to Beth-horon, that the Lord cast down* GREAT STONES *from heaven upon them unto Azekah, and they died: they were more which died with hail-stones than they whom the children of Israel slew with the sword.* Here the expression *great stones* is, perhaps, less ambiguous than *coals of fire*; yet the context hardly permits us to doubt, that these great stones were really hail-stones, or rather, perhaps, lumps of ice, formed in the atmosphere, such as occasionally fall in summer, and such as alarmed the whole of Paris and its neighbourhood, in July, 1788. At all events, the slaughter of the Canaanites is represented as resulting from the special interposition of divine power; and the consideration of miracles is irrelevant to our present purpose. In the New Testament, however, we find a passage, which may, perhaps, be construed as alluding, at least incidentally, to the traditionary fall of a meteorite; for, in the *Acts of the Apostles*, the chief magistrate of Ephesus is represented as thus addressing the people: *Ye men of Ephesus, what man is there that knoweth not how that the city of the Ephesians is a worshipper of the great goddess Diana, and of the image* WHICH FELL DOWN FROM JUPITER? or, more literally, OF THAT WHICH FELL DOWN FROM JUPITER. According to some learned commentators, this image was merely a conical or pyramidal stone, which fell from the clouds; and it appears that various other images of the heathen deities were nothing else. Thus, *Herodian* expressly declares, that the Phenicians had no statue of the sun, polished by the hand, but only a certain large stone, circular below, and terminated acutely above, in the figure of a cone, of a black colour, and that they report it to have fallen from the heavens. Nor is it at all surprising that rude and superstitious tribes should attach ideas of veneration and mystery to a solid and ignited body, precipitated from the sky. But even the complete silence of the sacred volume with respect to any physical appearance, does not imply its non-existence during the periods to which that volume refers; for scientific statements form no essential part of the plan of revealed religion; and stony bodies may have occasionally descended from the sky, in the peopled or unpeopled regions of the globe, as comets and eclipses may have attracted the attention of mortals, though not indicated by the inspired penman.

If from sacred we turn to the early periods of profane history, we shall find the annals of public events very copiously interspersed with notices of prodigies and strange appearances, many of which we may safely ascribe to the ascendancy which superstition long maintained over the human mind, so that it becomes extremely difficult, after the lapse of many ages, and in the collation of records which savour of the marvellous, to separate truth from fiction. Thus, in regard to the topic before us, we are fully authorised to discard from our ex-terrestrial catalogue certain modifications of sulphuret of iron, belemnites, orthoceratites, &c. which the observations of intelligent naturalits have proved to be of mineral or animal formation, as also the heads of arrows and sharpened flints, which have been fashioned by the hand of man, though the vulgar may, in the earlier stages of society, have attributed to them a celestial origin, and ranked them among *thunder stones*: but, when substances differing from these, and coinciding in any one character or circumstance with modern specimens of meteorites, are affirmed by the ancients to have fallen from the clouds, the remoteness of the epochs, and the lameness of the documents, may considerably affect our appreciation of the reputed evidence. Hence, when we touch much more lightly on the ancient than on some of the more recent testimonies, we are far from maintaining the certainty even of the particular instances selected; but, as the indiscriminate scepticism of the learned is scarcely less reprehensible than the blind credulity of the barbarian, we reckon it fair to admit their probability, and the weight which the mention of them may be considered as adding to that of subsequent and more circumstantial narratives.

Chronological History of Meteorites, interspersed with Remarks.

A. C. 1478. The thunder-stone in Crete, mentioned by *Malchus*. *Par. Chron.*—1200. Stones preserved in Orchomenos. *Pausan.*—1168. A mass of iron, on Mount Ida, in Crete. *Par Chron.*—705, or 704. The *Sacred Shield*, or *Ancyle*, which fell in the reign of Numa, of nearly the same shape with the mass that fell at Agram. But, if it really was of *brass*, and fell into *Numa's hands*, as mentioned by *Plutarch*, we may well suspect a *pious fraud*. 654. During the reign of Tullus Hostilius, a shower of stones fell on Mount Alba, and, when the senate deputed commissioners to ascertain the fact, they were assured that stones had really fallen, as thick as hail impelled by the wind. Similar events, adds the eloquent *Livy*, were celebrated by a festival of nine days. At that period, then, the fall of stones was solemnly recognized as a supernatural occurrence: the nature of the masses, however, is not particularly described; and, on subsequent occasions, the same historian has usually recourse to the general expression, *lapidibus pluere*, without farther comment or explanation.—644. According to *De Guignes*, the early historians of China make mention of five stones having fallen from the heavens, in the district of Song. 520. A stone fell in Crete, in the time of Pythagoras. *Calmet.*—466. *Pliny*, in the 58th chapter of the second book of his Natural History, commemorates the descent, in the day-time, of a stony mass, as large as a cart, and of a burnt colour, near Egospotamos in Thrace, and affirms that it was still exhibited in his time. The *magnitudine vehis* of this author may probably mean, that it was of such dimensions, that it could be conveyed in a cart; and some commentators read *vehibilis*. The Greeks pretended that it had fallen from the sun, and that Anaxagoras had predicted the day of its arrival on the earth's surface. Such a prediction, the naturalist observes, would have been more marvellous than the stone; and all knowledge, he adds, must be confounded, if either we admit the sun to be a stone, or a stone to fall from that luminary to the earth. Yet, whatever may have been the ingenious or the absurd surmises of those days, the reputed event became a subject of such notoriety, that the author of the Athenian Chronicle, a document published by Selden, along with the Arundelian marbles, formally places it under the 58th epoch, and in the 113th year of the Attic or Cecropian era. That Anaxagoras foretold the day of the fall, may as well be doubted, as that Sir William Herschel should have lent himself to the occupation of Moore the Almanac-maker: but we learn from a passage in the first book of Silenus, preserved by Diogenes Laertius, that the incident which we are now considering, suggested to the philosopher of Clazomene the hypothesis which he delivered to his disciples, namely, that the sky was a solid vault, composed of large stones, which its rotatory motion kept at a due distance from the centre, to which they would, otherwise, inevitably tend. We may also remark, that Pliny broadly asserts the frequent occurrence of the phenomenon—*decidere tamen crebro, haud erit dubium.* Some curious notices relative to the Thracian stone have likewise been preserved by Plutarch, in his Life of Lysander. It fell, he remarks, at Egospotamos, was of enormous dimensions, and was exhibited as a public spectacle by the people of the Chersonesus, who held it in great veneration. His account of the meteor is principally borrowed from Damachus or Daimachus, whom Strabo represents as addicted to fiction, and ignorant of geometry.

"During seventy-five successive days," says the biographer, "previous to the fall of the stone, a large fiery body, like a cloud of flame, was observed in the heavens, not fixed to one point, but wandering about with a broken, irregular motion. In consequence of its violent agitation, several flaming fragments were forced from it, which were impelled in various directions, and darted with the velocity and splendour of so many falling stars. After this body had alighted in the Chersonesus, and the inhabitants, recovered from their alarm, had assembled to see it, they could perceive no inflammable matter, nor the slightest trace of fire, but a real stone, which, though large, was nothing when compared to the volume of that fire-ball which they had seen in the sky, but appeared only as a piece detached from it." "It is obvious," continues Plutarch, "that Damachus must have very indulgent readers, if this account of his gains credit. If it is a true one, it completely refutes those who allege that this stone was merely a rock, torn by a tempest from the top of a mountain, and which, after being conveyed for some time in the air, by means of a whirlwind, settled on the first spot where the violence of the latter abated. This phenomenon, which lasted for so many days, was, perhaps, after all, a real globe of fire, which, when it dispersed, and became nearly extinct, might induce such a change in the air, and generate such a whirlwind, as might tear the stone from its native bed, and dash it on the plain."

Damachus, it is true, may, on this occasion, have given way to his love of the marvellous; and we can readily believe, that the seventy-five continuous days are either an error of the copyist, or an original exaggeration. When we reflect, however, that he is not the sole reporter of the occurrence, and that some of the circumstances which he specifies are very analogous to those which remain to be stated on less questionable authority, we can hardly refuse to acquiese in the presumption, that a meteorite really fell at the period, and on the spot, which are here so particularly specified.

465. The stone denominated *the mother of the gods*,

alluded to by so many ancient writers, and the source of so many learned, and so many foolish conjectures, is stated by *Appian*, *Herodian*, and *Marcellinus*, *to have fallen from heaven.* *Aristodemus*, quoted by the Greek scholiast on Pindar, asserts, that it fell, *encircled by fire*, on a hill, and at the feet of the Theban bard. It is said to have been of moderate dimensions, of a black hue, of an irregular angular shape, and of a metallic aspect. An oracle had predicted, that the Romans would continue to increase in prosperity, if they were put in possession of this precious deposit; and Publius Scipio Nasica was accordingly deputed to Attalus, king of Pergamus, to obtain and receive the sacred idol, whose worship was instituted at Rome, 204 years before the Christian era. According to *Valerius Maximus*, a stone fell in the March of Ancona: Livy even says, *lapidibus pluit*, which would intimate a shower of them.—343. A shower of stones near Rome. *Jul. Obseq.* 211.—*De Guignes* relates, that a *star fell to the ground* in China, and was *converted into a stone*—an event which created an extraordinary sensation. The inhabitants of the district, willing to convey a moral lesson to their unpopular emperor, caused these words to be engraved on the stone: *Chi-Hoang-Ty draws near to death, and his empire will be divided.* In the plenitude of his indignation, the emperor ordered all the inhabitants of the district to be put to death, and the stone to be broken in pieces; but he died in the course of the following year; and, three years after, in the reign of his successor *Eul-Chi-Hoang-Ty*, in consequence of a general revolt, the empire was partitioned into many kingdoms, and the dynasty of the Tsins was extinguished.—205, or 206. A shower of fiery stones. *Plut.*—192. A stone fell in China. *De Guignes.*—176. A stone is reported by *Livy*, to have fallen into the Lake of Mars, in the Crustumenian territory.—90, or 89. A shower of stones like bricks. *Plin.*—89. Two large stones fell at Yong, in China; and the noise of the explosion was heard over forty leagues. *De Guignes.*—56, or 52. Spongy iron in Lucania. *Plin.*—A shower of stones at Acilla, a town in Africa, mentioned in *Cæsar's Commentaries.*—38. Six stones fell in the province of Leang in China, *De Guignes.*—29. Four at Po, and two in the territory of Tching-ting-fou. *Id.*—22. Eight in China, *Id.*—19. Three in China. *Id.*—12. One at Ton-Korean. *Id.*—9. Two in China. *Id.*—6. Sixteen in Ning-Tcheou, and two at You. *Id.* We may believe, on the authority of De Guignes, that such notices are inserted in the records of China; but we are too little conversant in the literature of that singular country, to determine the precise quantity of credence that ought to attach to the notices themselves; yet, had no such events ever occurred in that part of the world, it is not very probable that they would have been so repeatedly and distinctly registered.

P. C. A stone in the territory of the Vocontii, deposited a little before Pliny saw it.—Mondognetius, in his Life of Marcus Aurelius, relates, that, in the reign of the Emperor Valentinian, such a copious shower of stones fell at Constantinople, that it killed most of the cattle in the fields, and even some people.—452. Marcellinus, an officer of the empire, and Count of Illyria, who lived in the reign of Justinian, and continued the chronicle of Jerome, from A. D. 379, to 534, makes mention of three large stones which fell from the heavens in Thrace; but he is silent as to particulars.—Nov. 5, or 6, 472. A great fall of black dust, probably at Constantinople, during which the heavens seemed to burn.—*Procop. Marcell. Theoph.* &c. Sixth century. Stones fell on Mount Lebanon, and near Emessa in Syria. Damascius, in an extract of his Life of Isodorus, preserved by Photius, relates that the former issued from *a globe of fire.*—About 570, a shower of stones, near Bender, in Arabia. *Alcoran.*—648. A fiery stone at Constantinople, according to several chronicles.—652. A shower of red dust at the same place. *Theoph. Cedren. Math. Eretz.*—811. In the third moon, on the day Wou-siu, between the third and fifth hour after mid-day, the sky being cloudy, and the weather cold, there appeared a globe of fire as large as a *hou*, (a measure of about ten bushels.) which fell between *Yan* and *Yun.* A noise, resembling thunder, was heard at the distance of many leagues, and the people fled with a violent outcry. Above the place where the globe fell, a reddish vapour remained, arranged like a serpent, and a *tchang* (nearly 12½ feet) in length; it remained till the evening, and then disappeared. *Ma-touan-lin.*—817. In the twelfth year, in the ninth moon, on the day Ki-kaï, about the third or fourth hour after mid-night, there appeared a running star towards the middle of the heavens; its head was like a bucket, and its tail like a bark of 200 *hou* burthen; it was more than ten tchang in length, and made a noise like a number of birds flying; it produced a light similar to that of the torches used in illuminations. It passed beneath the moon, moving towards the west; on a sudden, a great noise was heard, and at the moment the globe fell to the earth, a crash took place thrice as great as that of a falling house. *Id.*—823. A shower of pebbles in Saxony. *Mezeray*, and *Bonaventure de St. Amable.*—839. It is recorded in the history of Japan, that, in the sixth year of Nin-mio-teno, the 29th day of the eighth moon, there occurred at a place to the west of the town of Thean-tchhenan, where no fragment of stone previously existed, thunder and rain for ten days. The weather having become clear, stones similar to the points of arrows and to hatchets, were found on the earth, some being white and others red.—July, or August, 852. A stone fell in Tabaristan. *De Sacy*, and *Quatremère.*—Middle of the ninth century. Red dust, and matter like coagulated blood, fell from the heavens. *Kaswini*, *Elmazen.*—December, 856. Five stones fell in Egypt. *De Sacy*, *Quatremère.*—885, 886, and 887. Thunder-stones fell in Japan. *Ma-touan-lin.*—892 or 897. A stone fell at Ahmedabad. *Quatremère.*—905. Stones fell at Hoanglie, in Corée, which caused a noise like thunder. The officers of the place having sent these stones to the court, the president of the ceremonies assured the king that the phenomenon of falling stars had occurred so frequently, that it was no longer regarded as a prodigy. In China, certain stones of a black or violet colour are called *thunder-hatchets*, *scissors*, *hammers*, &c. according to their forms; and although they may have been wantonly multiplied, some of them are, probably, of meteoric origin. *Ma-touan-lin*, who registers the occurrences of falling stones in China, supposes that these thunder-stones are identical with them.—929. A fall of red sand, from a red sky, at Bagdad. *Quatremère.*—951. A stone fell near Augsburg, (not in Italy.) *Albertus Stadius*, and others.—Between 956 and 972. Platina, in his Life of Pope John XIII. enumerates, among the prodigies of the times, the descent of a very large stone during a furious tempest of wind and rain.—998. Cosmas and Spangenberg relate, that two large stones fell with an explosion like thunder, one of them alighting in the town of Magdeburg, and the other in the open country near the Elbe. —1009. Avicenna affirms, that when in *Djordjan*, (misrepresented *Lurgea* and *Cordova*.) he saw a sulphureous kind of stone fall from the atmosphere.—Between the 24th of July and the 21st of August, 1021, stones fell in Africa. *De Sacy*—1056. Red snow fell in Armenia. *Math. Eretz.*—1110. A burning body fell into the Lake of Van, in Armenia, and made its waters blood red, while the earth was cleft in several places, probably with stones. *Id.*—1112. Stones or iron fell near Aquileia. *Valvasor.*—1135 or 1136 Spangenberg and others inform us, that a stone as large as the human head was precipitated from the air at Oldisleben in Thuringia.—1164 George Fabricius, in the First Book of the History of Misnia, apprizes us of a shower of iron in that country, at Whitsuntide —1198. Stones fell near Paris *Henri Sauval*—July 26, 1249. Spangenberg and Rivander again mark the descent of stones in the neighbourhood of Quedlinburg, Ballenstaedt, and Blankenburg, in Saxony.—Thirteenth century. A stone fell at Wurtzburg. *Schotti Phys Cur.*—Between 1251 and 1363, stones fell at Welixoi-Ussing, in Russia *Gilb An.* —1280 A stone fell at Alexandria, in Egypt. *De Sacy.* —Oct. 1, 1304, Krantz, in his Account of Saxony, and several of the German Chroniclers, concur in stating, that many stones fell near *Friedland* or *Viedeland*, and that they did grea damage to the fields. But the *Friedland* of these authors, who probably copied from one another, is not sufficiently particularized, as there are many small towns and villages of that name. Spangenberg more pointedly mentions *Friedberg*, near the Saale.—1305. Burning stones fell in the country of the Vandals. *Bonav. de St Amable.*—Jan. 9, 1328. Stones fell in Mortahia and Dakhalia. *Quatremère.*—1360. Several stones were observed to fall from the clouds in Yorkshire. *Phil. Mag.*—1368 A mass of iron fell in the Duchy of Oldenburg. *Siebrand, Meyer.*—May 26, 1379. Stones fell at Minden, in Hanover. *Lerbecius.*—1416. Red rain in Bohemia. *Spangenberg.*

1438. According to Proust, the chemist, stones of a spongy texture were observed to fall near Roa, at no great distance from Burgos, in Spain; and, in support of his assertion, he quotes the ensuing extract of a letter from the Bachelor Cibdaréal.

"King Don Juan and his court being engaged in a hunting party, under the village of Roa, the sun was obscured by white clouds, and they saw descending from the air bodies which resembled grey and blackish stones, and of such considerable dimensions as to excite the greatest astonishment.

"This phenomenon continued during an hour, after which the sun reappeared, and the falconers, mounted on their horses, immediately repaired to the spot, which was not half a league distant. They reported to the king, that the field on which these stones lay, was so thickly strewed with them, of all sizes, as completely to conceal the soil.

"The king was desirous of visiting the scene, but his courtiers restrained him, by representing, that the place which heaven had selected for the theatre of its operations might be unsafe, and that it would be more advisable to detach one of his suite. Gomes Bravo, Captain of his Guards, volunteered his services, and brought with him four of these stones to Roa, whither the king had now retired. They were of a considerable size, some round, and as big as a mortar, others shaped like pillows or half fanego measures: but the circumstance which created most astonishment, was their extreme levity, for the largest did not weigh half a pound. They were of such a delicate texture, that they resembled sea-froth condensed more than any thing ese. You might strike your hand against them, without any apprehension of contusion, pain, or the least mark."

In respect of specific gravity, these stones must have differed very materially from the heavier specimens of recent date. From the fragility of their texture, no trace of their existence probably now remains; but the narrative, which bears all the marks of a genuine document, may be regarded as, in some measure, corroborative of the fall of the *spongy* masses, noticed by Pliny, and of the *fleecy* showers of that naturalist. In the present instance, too, no mention is made of any luminous appearance or explosion, and it is not even said that the masses felt hot when first touched.

Some time in the same century, a stone, and a mass like coagulated blood, accompanied by a *fiery dragon*, (meteor), fell near Lucerne. *Cysat.*—1480. Stones fell in Saxony and Bohemia. *Philos Mag.*—1491. A stone fell near Crema. *Simonetta.*

November 7, 1492.—The far-famed stone of Ensisheim has exercised the talents of contemporaneous writers, both in prose and verse. Professor Batenschoen, of the central school of Colmar, first directed the attention of naturalists to some of the old chronicles, which record the circumstances of its fall with much simplicity, and in the true spirit of the times The note which accompanied the stone, when it was suspended in the church of Ensisheim, may be rendered thus:

"In the year of the Lord 1492, on Wednesday, which was Martinmas eve, the 7th of November, there happened a singular miracle; for, between 11 o'clock and noon, there was a loud peal of thunder, and a prolonged confused noise, which was heard to a great distance, and there fell from the air, in the jurisdiction of Ensisheim, a stone which weighed 260 pounds, and the confused noise was, moreover, much louder than here. Then a child saw it strike on a field, situated in the upper jurisdiction, towards the Rhine and Inn, near the district of Gisgand, which was sown with wheat, and did it no harm, except that it made a hole there, and then they conveyed it from that spot, and many pieces were broken from it, which the Landvogt forbade. They, therefore, caused it to be placed in the church, with the intention of suspending it, as a miracle; and there came here many people to see this stone. So there were remarkable conversations about this stone, but the learned said that they knew not what it was, for it was beyond the ordinary course of nature that such a large stone should smite the earth to the depth of a man's stature, which every body explained to be the will of God that it should be found, and the noise of it was heard at Lucerne, at Villing, and in many other places, so loud, that it was believed houses had been overturned; and, as the King Maximilian was here the Monday after St. Catharine's day of the same year, his Royal Excellency ordered the stone which had fallen to be brought to the castle, and, after having conversed a long time about it with the noblemen, he said that the people of Ensisheim should take it, and order it to be hung up in the church, and not to allow any body to take any thing from it. However, his Excellency took two pieces from it, of which he kept one, and sent the other to the Duke Sigismond of Austria, and they spoke a great deal about that stone, which they suspended in the choir, where it still is; and a great many people came to see it." According to *Trithemius*, it fell with so much violence that it broke into two pieces, of which only the most considerable was suspended in the church. *Paul Lang* describes its form as corresponding to that of the Greek Delta, with a triangular point. Both of these writers lived at the period which they assign to the descent of this remarkable mass; and, although their names are fast hastening to obscurity, it behoves us to observe, that Trithemius yielded to few of his contemporaries in labour and learning, and that Lang, though a Benedictine monk, travelled in quest of historical monuments, and had the candour and boldness to arraign the license of the Roman Catholic clergy, while he applauded the independence of Luther and Melancthon. We may add, that Maximilian, who, shortly after this period, was elevated to the imperial dignity, in a Rescript dated Augsburg, November, 12, 1503, expressly refers to the stone in question, as having fallen in an open field before him, when he commanded the army which he had levied against the French; and that, availing himself of the apparently miraculous event, he exhorted the Germans to a new crusade against the Turks.

During the French Revolution, this large meteorite was found still suspended in the church, but it weighed only 171 lb. The French removed it to the National Library at Colmar, and, notwithstanding the many fragments which have been detached from it, the mass still weighs 150 lb A large specimen is preserved in the Cabinet of the Parisian Museum, another in the Imperial Cabinet at Vienna, and we have seen another small fragment in the valuable and interesting collection of Robert Ferguson of Raith, Esq.

The Ensisheim stone is of a schistose texture, of a slate-grey colour, and composed of small shining particles of granular portions of a whitish-grey, blended with thin laminæ of a slate-grey fissile substance of grains or globules of pure iron, and of grey and shining sulphuret of iron and nickel. The cross fracture is very unequal, and the longitudinal waving, in the direction of the laminæ, and, at the same time, tough and harsh. Such parts of the outer surface as remain entire are coated with a blackish vitrified crust. It gives no argillaceous odour by insufflation; and, under the blowpipe, the grey portions become black, and are converted into frit Its specific gravity is 3 23, and its analysis yielded to Vauquelin,

Silica	56.
Lime	1.4.
Magnesia	12.
Oxide of iron	30.
Nickel	2 4
Sulphur	3.5
	105.3

Its principal peculiarity, therefore, is its schistose texture.

January 28, 1496. Marcus Antonius Sabellicus, in the second volume of the Lyons edition of his works, (p. 341,) mentions the fall of three stones between Cesena and Bertonosi. Bonfinius, or rather, we presume, his continuator, reports, that a shower of stones fell near the village of Munkbergen in the course of the same year, and that the inhabitants amused their fancy by tracing on the fallen fragments outlines of the human countenance and diadems.—1501. According to different chronicles, showers of blood fell in several places.—1510. In the Commentary of Surius, a Carthusian monk of Cologne, mention is made of a shower of large stones in Lombardy, they are described, probably with some exaggeration, as harder than flint, smelling of Sulphur, &c. But the same event is more particularly commemorated by Cardan in his Treatise *De Rerum Varietate*; for he informs us, that between Cremasco or Crema, and Milan, and not far from the river Adda, at five o'clock in the evening, about twelve hundred stones fell from the air, one of which weighed 120 lb. and another 60 lb. Many were presented as curiosities to the French Governor and his Deputy. At three o'clock in the afternoon, the sky appeared as if in a general blaze, and the passage, though somewhat ambiguous, would lead us to infer, that the fiery meteor was visible for two hours. Like many of the learned and unlearned of his day, Cardan immediately connects the extraordinary appearance with the political transactions of his petty district. The same incident is noticed by Leonardus in his *Mirror of Stones*, and by Bondini in his *Theatrum Naturæ*. The following passage is extracted from a series of *Observations on Natural History, Meteorology*, &c. made in the early part of the 16th century, by Andrea da Prato of Milan, which, though not published, have been repeatedly copied in MS. It seems to allude to the same occurrence, although the year quoted is 1511.

"On the fourth of September, at the second hour of the night, and also at the seventh, there appeared in the air, at Milan, a running fire, with such splendour, that the day seemed to have returned, and some persons beheld the appearance of a large head, which caused great wonder and fear in the city. The same thing happened on the following night at the ninth hour. A few days after, beyond the river Adda, there fell from Heaven many stones, which, being collected at Cremasco, were found to weigh 8 lb and even 11 lb. each. Their colour was similar to that of burned stones." Dr Bossi, in commenting on this statement, endeavours to account for the space of time which appears to have intervened between the meteor and the fall of stones, by supposing it occupied in conveying the intelligence from Crema to Milan.

1516 In the year Wan-li, of the dynasty of Ming, in the 12th moon, on the 25th day, at Chun-khing-fou in the province of Soe-tchhouan, there was neither wind nor clouds, when the thunder rumbled suddenly, and six globular stones fell, of which one weighed eight pounds another fifteen, a third twenty-seven, the smaller not more than a pound, and the smallest of all only ten ounces *Ma-touan-lin*.—May, 1520, stones fell in Arragon *Diego de Sayas*.—April 28, 1540, a stone fell in the Limousin. *Bonav. de St. Amable*.—Between 1510 and 1550, Albinus in his Chronicle of Misnia, records the fall of a large ferruginous mass, in a forest near *Neuhof* between Leipsic and Grimma, in Saxony; but Jonston and Alberti write *Neuholem* others, *Naunhoff-Na* &c. A specimen of this mass is still to be seen in the imperial cabinet in Vienna. Some time about the same period, iron fell in Piedmont *Mercati* and *Scaliger*.—November 6, 1548. According to Spangenberg and Bonaventure de St. Amable, a blackish mass, accompanied with a red substance, like coagulated blood, and with a loud noise, fell at Mansfeldt in Thuringia.—May 19, 1552. From the same source we learn, that a shower of stones made great havoc in the environs of Schleusingen, also in Thuringia. That this was not a hail shower is obvious, from the circumstance that Spangenberg carried several of the stones with him to Eisleben.—1559. It is related in the 16th vol. of the *Breslaw Collection*, and in Isthuanfius's History of Hungary that five stones, said to be preserved in the treasury of Vienna, each of the size of a man's head, exceedingly heavy, of a rusty-iron colour, and emitting a strong smell of sulphur, fell from the heavens, with explosions and a dreadful concussion of the air, at Miscoz, in Transylvania.—Whitsuntide, 1560. Red rain at Embden, Louvain, &c. *Fromond.*—December 24 1560. A fiery meteor, and red rain at Lillebonne. *Natalis Comes.*—May 17, 1561. A stone fell at Eilenborg, in the Torgau. *Gesner* and *de Boot.*—May 27, 1580 Stones fell near Göttingen. *Bange.*—July 26, 1581. Between one and two o'clock in the afternoon, a stone, weighing 39 lb. of a blue and brownish colour, and which gave fire with steel, fell from the air, in Thuringia, with an explosion which shook the earth, and accompanied by the appearance of a small light, which was supposed to be a fire-ball, the heavens being, in other respects, serene. It sunk into the soil to the depth of a yard and a quarter, tossed up the earth to twice the height of a man; and was at first so hot that nobody could touch it. After some time had elapsed, it was carried to Dresden. Binhard's *Chronicle of Thuringia*, *Olearius.*—January 9, 1583, stones fell at Castrovillari. *Casto*, *Mercati*, and *Imperati.*—Ides of January, 1583. Mercati mentions, that some of the inhabitants of Rosa, in Lavadie, who were walking on the neighbouring heights, in serene weather, observed a thick black cloud, which exploded near them with such violence, that they fell almost senseless to the ground, and that, on recovering from their alarm, they immediately repaired to the spot, and found a stone of about 30 lb., which resembled iron —March 2, 1583. A stone, of the size of a hand grenade, fell in Piedmont.—1585. A stone fell in Italy. *Imperati.*—December 3, 1586. A great quantity of red and blackish matter, which burned some planks, and was accompanied by thunder and lightning, fell at Verden, in Hanover. *Solomon*, Senator of Bremen. —June 9, 1591. Angelus, in the *Annales Marchiæ*, and *Lucas* affirm, that some large stones fell at Kunersdorf. —1591. A shower of blood at La Magdelaine, near Orleans. *Leman*, in *Nouv. Dict. d'Hist. Naturelle.* —March 1, 1596, stones fell at Crevalcore, Mittarelli. Some time in the course of the sixteenth century, and not, as alleged, in 1603, a stone, exhibting metallic veins, is reported to have descended in the province of Valencia, in Spain. *Cæsius*, and the *Jesuits of Coimbra*, in their remarks on Aristotle's Meteorology —August, 1618, a great fall of stones, with a shower of blood, occurred in Styria. *De Hammer.*—1618. A metallic mass fell in Bohemia. *Kronland.*

April 17, 1620, the Emperor, Jehangire, in his Memoirs written by himself, in the Persian language, and translated by Colonel Kirkpatrick, from an old MS. thus relates the fall of a piece of meteoric iron.

"A. H 1030, or 16th *year of the reign.*—The following is among the extraordinary occurrences of this period.

"Early on the 30th of Furverdeen, of the present year,* and in the Eastern quarter (of the heavens,) there arose in one of the villages of the Purgunnah of Jalindher,† such a great and tremendous noise, as had nearly, by its dreadful nature, deprived the inhabitants of the place of their senses. During this noise, a luminous body (was observed) to fall from above on the earth, suggesting to the beholders the idea that the firmament was raining fire. In a short time, the noise having subsided, and the inhabitants having recovered from their alarm, a courier was dispatched (by them) to Mahommed Syeed, the Aumil‡ of the aforesaid Purgunnah, to advertise him of this event. The Aumil, instantly mounting (his horse,) proceeded to the spot (where the luminous body had fallen) Here he perceived the earth, to the extent of ten or twelve guz,§ in length and breadth, to be burnt to such a degree, that not the least trace of verdure, or blade of grass remained ; nor had the heat (which had been communicated to it) yet subsided entirely.

"Mahommed Syeed hereupon directed the aforesaid space of ground to be dug up ; when, the deeper it was dug, the greater was the heat of it found to be. At length, a lump of iron made its appearance, the heat of which was so violent, that one might have supposed it to have been taken from a furnace. After some time it became cold, when the Aumil conveyed it to his own habitation, from whence he afterwards dispatched it, in a sealed bag, to court.

"Here I had (this substance) weighed in my presence. Its weight was one hundred and sixty tolahs.‖ I committed it to a skilful artisan, with orders to make of it a sabre, a knife, and a dagger. The workman (soon) reported, that the substance was *not malleable, but shivered into pieces under the hammer.*¶

"Upon this, I ordered it to be mixed with other iron. Conformably to my orders, three parts of the *iron of lightning*** were mixed with one part of common iron ; and from the mixture were made two sabres, one knife, and one dagger.

"By the addition of the common iron, the (new) substance acquired a (fine) temper; the blade (fabricated from it) proving as elastic as the most genuine blades of Ulmanny,†† and of the South, and bending, like them, without leaving any mark of the bend. I had them tried in my presence, and found them cut excellently ; as well (indeed) as the best genuine sabres. One of these sabres I named *Katai*, or the *cutter ;* and the other *Burk-serisht*, or *the lightning natured.*

* "The first of Furverdeen of this year, (A. H. 1030,) corresponded with Saturday the 27th of Rubbi ul Akhir; consequently, the 30th of Furverdeen fell on the 26th of Jumad ul Oruvul, or, A. D. 1620"

† "A purgunnah is a territorial division, of arbitrary extent. The purgunnah of Jalindher is situated in the Punjaub, and about 100 miles S. E. of Lahore."

‡ "Aumil is a manager, or fiscal superintendant of a district."

§ "A guz is rather less than a yard."

‖ "A tolah is about 180 grains, Troy weight."

¶ "Literally, it did not stand beneath the hammer, but fell to pieces."

** "This expression is equivalent to our term *thunderbolt.*"

†† "The name of the place here designed, is doubtful."

" A poet* composed and presented to me, on this occasion, the following tetrastich.

" This earth has attained order and regularity through the Emperor Jehangire :

" In his time fell *raw* iron from lightning :

" That iron was, by his world-subduing authority,

" Converted into a dagger a knife, and two sabres."

But, what is more to our purpose, the late Hon. Charles Greville, at whose request Colonel Kirkpatrick translated the foregoing quotation, has remarked, that the Emperor Jehangire was not a prince on whom his courtiers would idly venture to impose; and that there can be little probability that an Aumil of a district should invent such a story, or be able to produce a substance like iron, but which, on trial, should differ from manufactured iron.

January 10, 1622, a stone fell in Devonshire. *Rumph.* —April 9, 1628, stones fell near Hatford, in Berkshire. *Gent Mag.*—December 6, 1631. The following letter from Captain William Badily, is inserted in the first volume of the Philosophical Transactions. " The 6th of December, 1631, being in the Gulf of Volo, riding at anchor, about ten of the clock that night, it began to rain sand or ashes, and continued till two of the clock next morning. It was about two inches thick on the deck, so that we cast it overboard with shovels, as we did snow the day before : the quantity of a bushel we brought home, and presented to several friends,† especially to the Masters of Trinity House. There was in our company, Captain John Wilds, Commander of the Dragon, and Captain Anthony Watts, Commander of the Elizabeth and Dorcas There was no wind stirring when these ashes fell ; it did not fall only in the places where we were, but likewise in other parts, as ships were coming from St. John d'Acre to our port : they being at that time a hundred leagues from us. We compared the ashes together, and found them both one."

October 27, 1634, stones fell in the Charollois. *Morinus.*—June 21, 1635. *Francesco Carli*, a learned, and highly respectable gentleman of Verona, reports the fall of a large stone at five o'clock in the evening. It was preceded by a great mass of flame, which traversed the Lago di Garda with such velocity, that the eye could scarcely follow its motions, illuminated all the country in the path of its passage, shaking the houses with its loud explosion, and alighting on the grounds of the Benedictine monks, under the town of Vago, about six Italian miles from Verona. Next morning there was found, on the spot on which it had alighted, a stone, invested with a black and channelled crust, which had penetrated about a yard into the soil, and was broken into several pieces, the largest of which was of a cubical form, of nearly a yard and a half on every side, of the colour of ashes, giving out an offensive odour of sulphur, and having minute particles of iron disseminated through its substance.

Saturday, July 7, 1635. During a violent storm, a stone, weighing about 11 oz fell at Calce. in the Vicentine territory. *Valisnieri*—March 6, 1636. During a perfectly serene sky, a large stone fell, with a loud crash, between Sagan and the village of Dubrow, in Silesia. It was covered with a crust, had, internally, the appearance of a metallic slag, and seemed as if it had been acted on by fire. *Lucas. Seschiche's Chron. Cluver. Geogr.*—1638. Red rain at Tourney.—November 29, 1639, (not 1629, nor 1627, as mis-quoted by some writers) In the third Section of the Second Book of his Physics, the celebrated Gassendi, whose accuracy and veracity will not be readily impeached, states, that, at ten o'clock in the morning, a stony mass, regarded as a thunder-stone, was seen by three creditable witnesses, to fall on Mount Vaision, one of the Maritime Alps, when the ground was covered with snow, and the sky perfectly serene. The spot is indicated as lying between the small towns of Guillaumes and Perne, in Provence. Many, for a great way round, heard the explosion, but only three individuals saw the fire-ball. The noise which preceded it, they compared to the repeated discharge of artillery ; but two of the concussions were particularly tremendous ; and the reverberation of the last was immediately followed by a rumbling noise, like the beating of four or five drums, when a flaming circle, of varied hues and apparently of four feet in diameter, passed before the eyes of the spectators, accompanied with a loud hissing, like that of fire-works, and with a strong sulphureous odour. So far as could be conjectured, it had rushed on their view when at the distance of only a hundred paces from their persons; and they saw it strike the ground, like a black-bird with white spots, and smoke issue from the place where it fell, which was not beyond thirty paces from their own station. The noise which ensued on its striking the ground, was compared to the firing of musketry. The inhabitants of both towns flocked to the smoking scene, and found a hollow of nearly one foot wide, and three in depth, the snow being melted for five feet round, and the earth and small stones obviously calcined. In the bottom of the hollow was found the stone, about the size of a calf's head, but rounder and more approaching, in form, to that of a man. It was of a dark metallic colour, extremely hard, and weighed 54 Provençal, or 38 Parisian pounds, its specific gravity being to that of common marble, as 14 to 11.

Mons. Izarn, not only mis-dates the year and day of this appearance, but asserts that Gassendi himself saw it; whereas that philosopher expressly says, *ipse cum abessem.*

August 4, 1642, a stone, weighing 4 lb. fell between Woodbridge and Aldborough, in Suffolk *Gent. Mag* —1643, or 1644. Stones fell in the sea. *Wurfhain.*—Jan. 23, or 24, 1645. Red rain fell at Bois-le Duc.—Oct. 6, 1646 Red rain at Brussels *Kronland, Wendelinus* — Feb. 18, 1647. A stone fell near Zwickau. *Schmid* — August, 1647. Stones fell in the bailliage of Stolzenau, in Westphalia. *Gilb. An*—Between 1647 and 1654, a stone fell into the sea. *Willmann, Malte-Brun.*—August 6, 1650. We find it mentioned in Senguerd's *Physical Exercitations*, that a stone fell at Dordrecht.—March 30, 1654 Thomas Bartholinus adverts to a shower of stones, in the island of Funen, in Denmark. A large stone fell at Warsaw. *Pet Borellus* A small stone fell at Milan, and killed a Franciscan monk. *Museum Septalianum.*—June 19, or 21, 1668. A great fall of stones near Verona. *Valisnieri, Montenari*, and *Carli* From a book which was printed at Paris, in 1672, and which

* " The poet is named in the original ; but the name is not perfectly legible."
† Some of the ashes were produced by Mr. John Evelyn, before the Royal Society.

has now become very scarce, entitled, *Conversations tirées de l'Académie de Mons l'Abbé Bourdelot, contenant diverses recherches et observations physiques*, par le Sieur Legallois, we make the ensuing extract:

"One of the members presents a fragment of two stones which fell near Verona, one of which weighed 800 pounds, and the other 200 pounds. These stones," he says, "fell during the night, when the weather was quite mild and settled. They seemed to be all on fire, and came from above, but in a slanting direction, and with a tremendous noise. This prodigy terribly alarmed three or four hundred eye-witnesses, who were puzzled what to think of it. These stones fell with such rapidity that they formed a ditch, which, after the noise and flame had ceased, the spectators ventured to approach, and examine them more nearly. They then sent them to Verona, where they were deposited under care of the Academy; and that learned body sent fragments of them to different places. This account induced the Society to consider the fragment in question with particular attention; and they remarked that it was of a yellowish colour, very easily reducible to powder, and that it smelled of sulphur." In the course of examining one of these stones, M. Laugier, professor of pharmacy at Paris, detected in it, by means of the caustic alkali, the presence of chrome.

February 27, 1671 Stones fell in Swabia. *Gilb. An.*—1673. Some stones fell in the fields near Dietling, and were deposited in the museum of Brackenhofer. *Leonardus de Gemmis*, and *Memorie della Societa Colombaria Fiorentina*.—October 6, 1674, Scheuzer affixes this date to the descent of two large stones in the canton of Glarus.—Between 1675 and 1677, a stone fell into a fishing boat near Copinsha, in the Orkneys. Wallace's *Account of Orkney*, *Gent. Mag* "The air and clouds here," says Dr. Wallace, "by the operation of the sun, do sometimes generate several things; as some years since, some fishermen fishing half a league from land, over against Copinsha, in a fair day, there fell down from the air a stone about the bigness of a foot-ball, which fell in the middle of the boat, and sprung a leak, to the great danger of the lives of the men that were in it, which could be no other than some substance generated in the clouds. The stone was like condensed or petrified clay, and was a long time in the custody of Captain Andrew Dick, at that time steward of this country; and Captain Dick, who is yet alive, told me he gave it to the late Earl of Glencairn." From these particulars, we can entertain little doubt of the fact, however much we may be disposed to smile at the Doctor's facility of theorizing.

March 26. O. S. 1676. About an hour and three quarters after sun-set, a fire ball was seen to proceed, as if from Dalmatia, passing obliquely over Italy with a hissing noise, and exploding to the south south-west of Leghorn with a terrible report. Its fragments are said to have fallen into the sea, with the same sort of noise as when red hot iron is extinguished in water. Its greatest altitude in the south south-east at Bologna, was 38°, and its greatest at Siena, in the north north-west, was 58° On one side of the country it seemed to be nearly vertical, at Rimini and Savigniano, and at Leghorn on the other. Montanari professor of mathematics at Bologna, who published a treatise on this phenomenon, conjectures that the meteor must have moved at the rate of at least 160 miles in a minute. Its apparent magnitude at Bologna exceeded that of the full moon in one diameter, and was above half as big again in the other. Dr. Halley has condensed the substance of Montanari's Report, in No. cccxli. of the *Philosophical Transactions*.

May, 28, 1677. Many stony masses, supposed to have contained particles of copper, are said by Balduinus, in his Appendix to the *Miscellanea Naturæ Curiosorum*, for 1677, to have fallen near Ermendorf, in Saxony.—January 12, 1683, a mass of stone or iron fell near Castrovillari, in Calabria. *Mercati*.—March 3, 1683. A stone fell in Piedmont. *Id.*—1689.—Red dust fell at Venice, &c. *Valisnieri*—Jan. 3, 1697 In Soldani's catalogue, published in the 9th vol. of the *Transactions of the Academy of Sciences at Siena*, stones resembling those already described are said to have fallen at Pentolina, near Siena.—May 19, 1698. Scheuzer, in his *Natural History of Switzerland*, informs us that a black stone fell from the atmosphere, with various explosions, near the village of Waltring, in the canton of Berne, and that it was transmitted, with an account of the circumstances, to the public library at Berne. It is doubtful, however, if the stone preserved in that repository is the same which fell.—June 7, 1706, a stone, weighing 72 lb. is said to have fallen near Larissa, in Macedonia. It was observed to proceed from the north with a loud hissing, and enveloped in a small cloud, which exploded with a tremendous noise discharging a stone, which had the appearance of iron dross and the smell of sulphur. *Lucas*.—May 5 and 6, 1711. Red rain at Orsio, in Sweden. *Act. Liter. Suec.* A gelatinous matter fell with a globe of fire, in the isle of Lethy, in India. *Barchewitz*.—April 6, 1719, there fell into the Atlantic Ocean, in 45° Lat N. and 322° 45′ Long. from Paris, a shower of sand, which lasted from ten o'clock in the evening till one o'clock of the afternoon of next day. It was preceded by a luminous meteor. The wind was then east south-east. The captain of a vessel, and all the crew, certified the fact to Father Feuillée, who presented a specimen of the sand to the Academy of Sciences. It had the appearance of common, but very fine sand. June 5, 1722, stones fell near Scheftlas, in Freisengen. *Meichelbeck*—June 22, 1723 Dr. Rost (*Breslaw Collect*) relates, that at two o'clock in the afternoon, the weather being then calm, there was seen at Pleskowicz, some miles from Reichstadt, in Bohemia, a small cloud, from which several large and small stones were projected, under loud explosions but without any lightning. These stones, which were black on the outside had internally the appearance of metal, and exhaled a strong sulphureous odour. Twenty-five of them were collected in one place, and seven or eight in another. This instance is likewise noted by Stepling, *de Pluvia Lapidea*—July 22, 1727. Stones fell at Lilaschitz, in Bohemia. *Stepling*—1731. Fused metal fell at Lessay. *Halley*—August 18, 1738. Stones fell near Carpentras. *Castillon*—Oct. 25, 1740 Stones fell at Rasgrad *Gilb. An*—1740, or 1741. A large stone fell, during winter, in Greenland. *Egede*.—1743 Stones fell at Liboschitz, in Bohemia *Stepling*.—1744. Red rain at San Pietro d'Arena, near Genoa. *Richard*—October 12, 1750 M. de Lalande, the celebrated astronomer, informs us that a loud noise was heard in Lower Normandy, and that a very large mass of stone fell at Niort, in the vicinity of Coutances.

May 26, 1751, at six o'clock in the evening, a remarkable fire-ball was observed near Hraschina, in the district of Agram, in Upper Sclavonia. According to

Mr. Stutz, an intelligent naturalist, attached to the Imperial Cabinet of Vienna, this meteor burst asunder into two parts, exhibiting the appearance of twisted chains of fire, accompanied with smoke, rushing down with a dreadful explosion, and with such force as to shake the earth. The larger fragment, which weighed 71 lb. sunk to the depth of three fathoms, and made a breach of two feet, round which the soil was greenish, and seemed to be scorched with fire. The other, of only 16 lb. weight, fell in a meadow at 2000 paces from the first, and made an opening of four feet wide. The largest, which consists of native iron, and presents on its surface the most evident marks of fire, is preserved in the Imperial Cabinet of Natural Curiosities at Vienna, with an official attestation from the consistory of the bishopric of Agram, who interrogated several eye-witnesses A great many people in that part of the country heard the explosion, and likewise saw some fiery body fall from the sky, though, on account of the distance, they could not determine the precise spot. Dr. Chladni and Dr. Noehden mention, that they saw the larger mass in the Vienna museum; and the latter remarks, that it is not smooth and even on the outside, but rough, with depressions and protuberances, and destitute of the vitreous particles observable in the cavities of the Siberian iron. Klaproth's analysis gave of native iron 96.5, and of nickel 3.5—a composition nearly identical with the specimen of native iron brought by Humboldt from the province of Durango, in Mexico.

January 1753. A stone fell at Eichstadt, in Germany. *Cavallo.*—July 3 1753. Four stones, one of which weighed 13 lb fell at Strkow, near Tabor, at eight o'clock in the evening, when the air was tranquil, and the sky little shaded with clouds. Their fall was preceded by three loud and prolonged peals, like the discharge of artillery The people in the fields fled for terror to their houses or climbed up into the trees; and a shepherd, who applied his hand to one of the stones after it had fallen, felt it very sensibly heated. A fragment of one of them was distinctly labelled in the Bornian collection, with the additional annotation, *Quæ fragmenta 3tio Julii, 1753, inter tonitrua, e cælo pluisse creduliores quidam asserunt.* The expression of *creduliores quidam*, may be alleged to invalidate the purport of the label, yet it deserves to be remarked, that, in regard to the present subject of our inquiry, what was formerly accounted the credulity of the vulgar, may now, on several occasions at least, be construed into probability, if not into matter of fact, that Stepling reported the phenomenon only the year after it is stated to have taken place, and that the late Hon. Charles Greville, who procured the identical specimen from the Bornian collection, and Mr. Howard, found it to coincide in composition with other atmospheric stones; for its analysis gave,

Silica	45
Magnesia	17 27
Iron	42 72
Nickel	2.72
	107 7

Its specific gravity is 4.28. Another specimen is deposited in the Imperial Cabinet of Vienna

September, 1753. We have next to direct our attention to another report of M. de Lalande, inserted in the *Historical Almanack of Bresse*, for 1756. About one o'clock, P. M. when the weather was very hot, and very serene, without any visible trace of a cloud, a very loud noise, like the discharge of two or three cannons, was heard within the circumference of six leagues, but for a very short duration. This noise was loudest in the neighbourhood of Pont-de-Vesle; and at Liponas, a village three leagues from the last mentioned place, it was even accompanied by a hissing like that of a cracker. On the same evening there were found two blackish masses, of a form nearly circular, but very uneven, which had fallen, the one at Liponas, and the other at Pin, into ploughed ground, and sunk, by their own weight, to half a foot beneath the surface. One of them weighed about 20 lb. and a fragment of the other weighing 11½ lb. was preserved in the cabinet of M. Varenne de Beost, at Dijon. The basis of these masses resembled a greyish trap, and was very refractory; and through the substance of the stone, and especially in its fissures, were disseminated some ferruginous particles in grains, filaments, or minute nodules. This iron, when subjected to a red heat, became obedient to the magnet. The black coating on the surface M. de Lalande ascribed to fusion, induced by violent heat. These circumstances, though slightly noticed, are strictly conformable to the history of more recent cases, which remain to be detailed.

July, 1755. A stone fell at Terra nuova, in Calabria, which weighed 7 oz. *Domin. Tata.*—October 20, 1755. A black dust, like lamp-black, fell in Shetland between three and four o'clock in the afternoon, when the sky was very hazy. This dust smelled strongly of sulphur, and covered the faces and hands, and blackened the linen of the people in the fields. As the wind blew from the south-west, it is not probable that it was ejected from Hecla, which is situated between 500 and 600 miles farther north. *Phil. Trans.* vol l.—Nov. 15, 1755 A red sky, and the fall of red rain, in several countries. *Nov Act Nat Cur* t. ii —Oct. 9, 1763 Red rain at Cleves, Utrecht, &c. *Mercurio. Histor. Polit* —Nov. 14, 1765. Red iron in Picardy. *Richard.*—End of July, 1766. When the sky was clear at Albereto, in the neighbourhood of Milan, it was dark and cloudy in the direction of the western hills, and in the valley to the north, with frequent thunder and lightning. About five o'clock in the evening, when the peasants were dispersed over the fields, engaged in their rural labours, there was suddenly heard, not only in Albereto, but in other places at a considerable distance to the west, and even at Modena, an unusual noise, like the discharge of artillery, succeeded by a whizzing in the air, like that produced by a cannon bullet when powerfully propelled. The Duke of Modena's gardener even believed that a cannon ball was descending into the garden. Others either did not hear the whizzing noise, or had not paid attention to it. In Albereto, however, it was not only heard, but a body was moreover seen traversing the air with great velocity, and falling abruptly to the earth. To some of the distant bystanders it appeared in a state of ignition; but to two ladies, who were within a mile of the spot, it seemed opaque and smoaking. They instinctively clung to a branch of a tree, but an ox, which was near them, fell to the ground from terror. The stone, which diffused an odour of sulphur, had penetrated the soil to nearly the depth of a fathom, was still hot when taken up, and had the appearance of a sandstone of great weight, of an irregular triangular figure, with its external surface uniformly burnished over with black, as if from the effect of fire. The person who took it up broke it into pieces, and the fragments were distributed among different people in the town. Father Troili, who relates these circumstances, as they were communicated to him by eye-witnesses, and particularly by the individual, who, with the assistance of a young peasant, extracted the stone from the earth, published in the course of the same year a curious treatise, entitled, *Della Caduta di un Sasso dall'Aria Ragionamento*, &c. in which he adduces many excellent arguments to prove not only his own assertions, but the truth of the general doctrine of the descent of meteorites on various occasions. But we cannot learn that the reasoning of the Jesuit produced much impression on the public mind; and certainly it had no weight with men of science. At the distance of half a century, however, the book has been eagerly coveted by the learned; and a copy, with the perusal of which we have been politely favoured by Thomas Allan, Esq. of this city, belongs to that gentleman's valuable repository. Vassalli, in his *Physico Meteorological Letters*, alludes to the fall of the Albereto stone; and Beccaria likewise adverts to it in the postscript of his letter to Dr. Franklin, entitled, *De Electricitate Vindice*, having apparently procured his information of the fact from Fogliani, bishop of Modena, a highly respectable character, and a zealous naturalist. —August 15, 1766. Between six and seven o'clock P. M. a small stone fell near Novellara, at a little distance from a poplar that was struck at the same time by lightning. But if Troili, who mentions the fact, be correct in his conjecture, it was a piece of the bark of the poplar vitrified by lightning,—a supposition which seems to be scarcely admissible.

Sept. 13, 1768. The Abbé *Bachelay* acquaints us, that, about half past four o'clock in the afternoon, there appeared near the castle of Chevalerie, in the neighbourhood of Lucé, a small town in the province of Maine, a stormy cloud, from which proceeded a peal of thunder, like the discharge of a cannon, which was succeeded by a sound so similar to the lowing of cattle, as to impose on several people who heard it, in a circuit of two leagues and a half, but unaccompanied with any perceptible flame. Some reapers, in the parish of Perigué, about three leagues from Lucé, on hearing the same noise, looked up, and saw an opaque body, which described a curve, and fell on soft turf on the high road, near which they were at work. They all quickly ran up to it, and found a sort of stone, nearly half of which was buried in the earth, and the whole so hot that it could not be touched. At first they fled in a panic; but, on returning to the spot some time after, they found the mass precisely in the same situation, and sufficiently cooled to admit of being handled and narrowly examined. It weighed seven pounds and a half, and was of a triangular form, presenting as it were three rounded horns, one of which, at the moment of the fall, had entered into the ground, and was of a grey or ash-colour, while the rest which was exposed to the air was very black. When the Abbé presented this stone to the Academy of Sciences, that body appointed Messrs. Lavoisier, Fougeroux, and Cadet, a committee, to examine and analyse it, a task which they performed with more care and accuracy than M. de Lalande had done on a preceding occasion; but their trial was limited to an integral part of the whole, considered as a homogeneous substance, in place of being applied to each of the constituent parts. The result was

Silica	55.5
Iron	36
Sulphur	8
	99.5

The substance of the stone was of a pale ash-grey, speckled with an infinite number of minute and shining metallic points, visible through a magnifying glass. The thin black outer coating, which seemed to have been fused, alone gave a few sparks when struck with steel. Its specific gravity was 3.58. From the few small fragments of this meteorite which have been preserved, it seems to be nearly allied to those from Benares. The committee, very unwilling to allow that it could have descended from the air, conjectured that it had previously existed in the ground, and had merely been struck by the electric flash. The singular position in which it was found, however, with one of its angles inserted in the turf, was most likely not a permanent one: and really with respect to a matter of fact, subject to the cognizance of the senses, we may believe a rustic spectator, in preference to a philosopher who speculates in his closet.

Another stone, of nearly the same composition, accompanied by the history of its fall at Aire, in Artois, was presented to the academy in the course of the same year, by M. Gusson de Boyaval, honorary lieutenant-general of the bailliage of Aire, to which was added, by the younger Morand, the specimen from Coutances. According to the academical report, these three stones, when compared, presented no difference to the eye, being of the same colour, and nearly of the same grain, interspersed with metallic and pyritous particles, and covered with a black and ferruginous incrustation. Their common aspect did not convince the academy that they had been conveyed to the earth, yet the coincidence of the attested circumstances in three places, distinctly separated from one another, and the characters which discriminated them from other stones, induced the learned body to announce their history, and to invite its discussion.

November 20, 1768. A stone fell at Mauerkirchen, near the Inn, in Bavaria, at four o'clock, P. M. which weighed thirty-eight pounds. It was of a triangular form, and eight inches in thickness. Its fall was proclaimed by a hissing noise, and great darkness in the air, and it penetrated two feet and a half into the soil. *Imhof, in Gilb. An.*—A detached fragment is preserved in the Imperial Cabinet of Vienna, another in the Grevillian Collection, and another in that of Robert Ferguson of Raith, Esq.

November 17, 1773, the Captain general of Saragossa dispatched the following letter, accompanied with the stone to which it refers, to Don Manuel de Roda, Minister of State.

"In November last, an extraordinary occurrence, said to have happened on the 17th of that month, in a ploughed field at Sena, a village in the district of Sigena, was the topic of conversation in this city.

"The sky being perfectly serene, three reports, resembling those of cannon, were heard, and followed by the fall of a stone, weighing nine pounds and one ounce, at a little distance from two labouring men. One of them went up to it; but the strong smell which it emitted stopped him for a moment.

"Recovering from his surprise, he went nearer, heaved it up with his spade, and waited till it was sufficiently cold for him to carry it to the village, where he delivered it to the priest.

"From inquiries made immediately afterwards on the spot, and among the people in the neighbourhood, it appears that the noise in the air and fall of the stone were not accompanied with any storm or with lightning."

This stone is still preserved in the Royal Collection at Madrid. Professor Proust, who was allowed to analyse it, on condition of leaving the principal portion untouched for the gratification of the curious, has favoured the public with several particulars relative to its texture and aspect. When delivered to him, it weighed six pounds ten ounces. Along with it was a piece of three or four ounces, the only one remaining of those which had been broken from it by the inquisitive. It was interspersed with spots of rust, both externally and internally, owing probably to its having been immersed in water, to try the effect of that fluid on its composition. Its shape was an irregular oval, seven or eight inches long, four or five broad, and four in its greatest thickness. One side was flattish, a little depressed in the middle, and much rounded on the edges. It appeared to have had the black vitreous crust common to stones of this kind, though from its fragility the greater part had fallen off in passing through many hands, and receiving occasional blows, so that none remained except in the hollow of the base, and a little on the faces of the pyramid. On examining this crust, it was judged to be the effect of heat, powerful, though momentary, because the metallic and sulphureous particles immediately beneath the crust had not had time to change colour, or even to lose their lustre. It had the porousness of an aggregate mass of arenaceous particles, without any cement, so that the breath would easily pass through a piece held between the teeth; nor did it give sparks with steel. Its colour was a uniform bluish-grey, like that of a black substance, enlightened by a white one, or like the hue of an earthy compound, tinged by the least oxydation of iron. The rounded oval grains, of which the mass was composed, were very small, the largest being scarcely bigger than hempseed, among which were sprinkled metallic and sulphureous particles, characterized by that light tint of kupfernickel, observable in most meteorites. The microscope ascertained that the earthy grains, so far from having been fashioned by the movement of water, were globules, rough with crystalline or reflecting points, so that they could not be confounded with common sand. A piece of about two inches being exposed to a red heat, in a crucible, for half a quarter of an hour, was much changed; for the sandy globules became of a darker grey, and the metallic particles, deprived of their lustre, were sensibly oxidized. About two ounces were heated for half an hour, in a forge fire, which converted the stone into a semi-vitreous mass, blackish, slightly porous, and interspersed with globules of iron, which had not time to precipitate, though upwards of 100 grains of regulus were collected at the bottom. The magnetic iron was not uniformly mixed in the mass, as some parts yielded 22, and others only 17 per cent. This iron was combined with nickel, in the proportion of about 3 per cent.; but no nickel was traceable in any other part of the stone. After this alloy was separated by the magnet, the remainder was found, by analysis, to contain of

Iron, sulphureted at a minimum,	12
Black oxyd of iron,	5
Silex,	66
Magnesia,	20
Lime and magnesia in quantities too small for appreciation.	
	103

A fragment kept for twelve hours under water, was taken out, covered with spots of rust, which distinguished the grains of alloy from the sulphureous particles with which they were formerly confounded.

September 19, 1775. A stone, which is still preserved in the Cabinet of Natural History at Cobourg, fell near Rodach, a village in the principality of that town. *Gilb. An.*—1775, or 1776. Stones fell near Obruteza, in Volhynia, *Id.*—January or Feburary 1776, a great shower of stones fell near Fabbriano, in the territory of Santanatoglia, the ancient duchy of Camerino. *Soldani* and *Amoretti.*—1779. Mr. Bingley relates, in the *Gentleman's Magazine*, that he has in his possession two pieces of an atmospheric concretion, which actually descended in a loud peal of thunder on a meadow at Pettiswood, in the county of Westmeath, Ireland. They weigh three ounces and a half, and are supposed to have formed two-thirds of the whole mass, which in shape resembled a twopenny heart-cake. "At the instant this rude lump descended," says Mr. Bingley, "our little village was enveloped with the fumes of sulphur, which continued about six minutes. To its descent five witnesses are now living, three of whom reside in London. It lighted upon the wooden part of a harness, called a stradle, belonging to a filly drawing manure to a meadow, and broke into three pieces. At the same instant the affrighted beast fell to the earth under her load; as did the two equally affrighted gassoons (boys,) the drivers, who in *good Irish* came crying to me with two pieces of the stone, declaring that themselves and the filly were all *murdered by this thunder bolt*; none of whom, however, have received the least injury. The two pieces, when I received them after the *resurrection* of the boys, were warm as milk just from the cow; whence it may naturally be concluded that the cake came from a scorching atmosphere, and pretty well accounts for the outside of it in its formation, and during its stay there, having been tinged to a whitish brown, whereas internally it is of a silver white."—April 11, 1780. Stones fell near Beeston, in England. *Loyd's Evening Post.*—April 24, 1781. Count *Gioeni* observed in the third region of Mount Etna, every thing to be wetted with a cretaceous grey rain, which, after evaporation, left every part covered with it, to the height of two or three lines. All iron work touched by it became rusty. *Philos. Trans.* vol. lxxii.—1782. A stone fell near Turin. *Tata* and *Amoretti.*—February 19, 1785. Baron *Moll*, in a German publication, has communicated some notices of stones which fell in the principality of Eichstaedt. One of the masses transmitted to Baron Hompesch had the aspect of a grey ash-coloured sandstone, speckled with small grains of both malleable and ochreous iron. A brickmaker saw it fall when the ground was covered with snow, and immediately consequent on what he termed a loud peal of thunder. On running to lay hold on it, he felt it so hot, that he was obliged to let it cool in the snow in which it was immersed. This specimen was about half a foot in diameter, and completely enveloped in a black vitrified incrustation of native iron, ten lines in thickness, which indicated the action of fire. It yielded to Klaproth,

A specimen may be seen in the Imperial Cabinet of Vienna. See also *Pickel* and *Stutz*.—October 1, 1787. Stones fell in the province of Charkow, in Russia. *Gilb. Ann.*

July 24, 1790. The shower of stones which fell near Barbotan and other places in the *landes* of Bourdeaux, is worthy of particular commemoration. The fiery meteor from which it proceeded, and which was seen at Agen, and in the neighbouring departments, about nine o'clock in the evening, after traversing a certain portion of the atmosphere, and dragging a luminous train, which was visible for at least 50 seconds, exploded with an extraordinary noise and scintillation. Of the numerous accounts of this phenomenon, some of the most interesting are addressed to M. Darcet, the chemist. An inhabitant of St. Sévère, for example, imparts the ensuing circumstances.

"Yesterday our town's people were agitated by a very unusual alarm. About a quarter past nine o'clock, there suddenly appeared in the air a fire-ball, dragging a long train, which spread a very vivid light over the horizon. This fire-ball soon disappeared, and seemed to fall at one hundred paces from us. Soon after we heard an explosion, much louder than that of cannon or of thunder. Every body dreaded being buried under the houses, which threatened to give way, from the violence of the concussion. The same phenomenon was seen, and the report heard in the neighbouring towns, such as Mont du Marsan, Tartas, and Dax. In other respects the weather was very calm, without a breath of wind or a cloud, and the moon shone in all her brightness."

M. Darcet's brother, a clergyman in that part of the the country, sent him a small stone, which was picked up on the morning after the explosion, and the history of which he was scrupulously anxious to investigate. Being satisfied with respect to all the particulars, he dispatched it to Paris, accompanied with some curious remarks. "When the stones fell," he observes, "they had not their present degree of hardness. Some of them fell on straw, bits of which stuck to the stones, and incorporated with them. I have seen one in this predicament. It is at present at la Bastide, but I cannot persuade the owner to part with it.... Those which fell on the houses, produced a noise not like that of stones, but rather like that of a substance which had not yet acquired compactness."

We shall also cite the *procès verbal*, a simple but authentic document.

"In the year one thousand seven hundred and ninety, and the 30th day of the month of August, we, the Sieur Jean Duby, Mayor, and Louis Maullon, Procurator of the Commune of the Municipality of La Grange de Juillac, and Jean Darmitte, resident in the parish of la Grange de Juillac, certify in truth and verity, that on Saturday the 24th of July last, between nine and ten o'clock, there passed a great fire, and after it we heard in the air a very loud and extraordinary noise; and about two minutes after there fell stones from heaven; but fortunately there fell only a very few; and they fell about ten paces from one another in some places, and in others nearer, and finally in some other places farther, and falling, most of them of the weight of about half of a quarter of a pound each; some others of about half a pound, like that found in our parish of la Grange; and on the borders of the parish of Creon, they were found of a pound weight, and in falling they seemed not to be inflamed, but very hard and black, without and within, of the colour of steel; and, thank God, they occasioned no harm to the people nor to the trees, but only to some trees which were broken on the houses; and most of them fell gently, and others quickly, with a hissing noise; and some were found which had entered into the earth, but very few. In witness whereof we have written and signed these presents.

Duby, *Mayor;* Darmitte."

M. Baudin states, that as Mr. Carris and he were walking in the court-yard of the castle of Mormés, about half past nine o'clock in the evening, when the air was quite calm, and the sky cloudless, they found themselves suddenly surrounded by a pale clear light, which diminished that of the nearly full moon. On looking up, they observed, almost in their zenith, a fire-ball of a larger apparent diameter than that of the moon, dragging a tail five or six times longer than its body, and which gradually tapered to a blood red point, while the rest of the meteor was of a pale white. The direction of this luminous body, which proceeded with great velocity, was from south to north. In about two seconds, it split into portions of considerable size, which fell in different directions, like the fragments of a bomb that bursts in the air. These fragments became extinguished before they reached the ground, and some of them, in falling, assumed that blood red colour which had been observed at the point of the tail. Two or three minutes after, they heard a dreadful explosion, like the simultaneous firing of several pieces of ordnance. The concussion of the atmosphere produced effects similar to those of an earthquake; for windows shook in their frames, and kitchen utensils were thrown down from their shelves; but M. Baudin and his friend were not sensible of any motion under their feet. From the court of the castle these gentlemen went into the garden, when the noise still continued, and seemed to be directed over their heads. Some time after it had ceased, they heard a hollow sound rolling in echoes, for fifty miles, along the chain of the Pyrenees, continuing for four minutes, and gradually dying away in distance, the atmosphere all the time diffusing a sulphureous odour.

The interval which occurred between the bursting of the meteor and the loud report, induced M. Baudin to conjecture that the fire-ball must have been at least eight miles from the earth's surface, and that it fell about four miles from Mormés; and the latter part of his conjecture was confirmed by the fact. It appears, indeed, from the concurring relations of intelligent persons worthy of credit, that the meteor really exploded at a little distance from Juillac, and that the fallen stones, of different sizes, were found lying in an almost circular space of nearly two miles in diameter. Though some of them fell in courts and gardens, no houses were materially injured; but, in the neighbouring woods, some branches were broken and torn off. According to some of the accounts, one of the stones fifteen inches in diameter, broke through the roof of a cottage, and killed a herdsman and a bullock. People deserving of credit, mentioned that one of four pounds had fallen near a farmer's door; and another, which weighed between twenty and twenty-five pounds, was carried as a curiosity to the town of Mont-du-Marsan. Though generally smooth on the outside, they presented some longitudinal cracks or fissures, while their internal substance, transversely striated, exhibited indications of metallic veins, especially of a ferruginous complexion. When yet red hot, and scattered in various directions, they formed that magnificent fire-work, that shower of flame, which illuminated the horizon over a large track of country. The meteor is supposed to have been perpendicular to Juillac, since at Dax, situated to the south-west of Messin, it was perceived in the north-east. It was seen at Bayonne, Auch, Pau, Tarbes, and even at Bourdeaux and Toulouse, though at the last mentioned place it excited little attention, on account of its great distance, and its appearing only a little brighter than a shooting star.

When all the circumstances of the case are duly considered, we need not be surprised that the publication of them should produce conviction on the minds of many men of science, who had avowed their disbelief in every thing of the kind. In fact, when we are presented with the joint testimony of the learned and unlearned of the district, in which the phenomenon is stated to have occurred, when we find the Professor of Natural History in the central school of Agen retracting his former scepticism, and the accurate and skilful Vauquelin revealing the same chemical substances which he had detected in other atmospheric stones, and nearly in the same proportions, it would be highly unreasonable to withhold our assent, merely because we have not in person witnessed the particulars. The few apparent discrepancies which may be observed in the different accounts, are all capable of an easy solution, and ought in no respect to invalidate the testimony in favour of the general fact; yet, it is not a little singular that different narratives, published at no great distance of time subsequent to the event, assign to it erroneous dates, some placing it in 1789, others in 1791, some in August, and others in September. Specimens of the Barbotan stones are not uncommon in the collections of the curious.

May 17, 1791. Stones fell at Castle Berardenga, in Tuscany. *Soldani.*—June 16, 1794, the late *Earl of Bristol's* account of the Siena meteorite is thus related by the late *Sir William Hamilton*, in the *Philosophical Transactions* for 1795.

"I must here mention a very extrordinary circumstance indeed, that happened near Siena, in the Tuscan State, about eighteen hours after the commencement of the late eruption of Vesuvius, on the 15th of June, although that phenomenon may have no relation to the eruption; and which was communicated to me, in the following words, by the Earl of Bristol, Bishop of Derry, in a letter, dated from Siena, July 12, 1794. 'In the midst of a most violent thunder storm, about a dozen stones of various weights and dimensions fell at the feet of different people, men, women, and children; the stones are of a quality not found in any part of the Sienese territory; they fell about eighteen hours after the enormous eruption of Vesuvius, which circumstance leaves a choice of difficulties in the solution of this extraordinary phenomenon; either these stones have been generated in this igneous mass of clouds, which produced such unusual thunder; or, which is equally incredible, they were thrown from Vesuvius, at a distance of at least 250 miles; judge then of its parabola. The philosophers here incline to the first solution. I wish much, sir, to know your sentiments. My first objection was to the fact itself; but of this there are so many eye-witnesses, it seems impossible to withstand their evidence, and now I am reduced to perfect scepticism.' His lordship was pleased to send me a piece of one of the largest stones, which, when entire, weighed upwards of five pounds; and I have seen another, which has been sent to Naples entire, and weighs about one pound. The outside of every stone that has been ascertained to have fallen from the cloud near Siena, is evidently freshly vitrified, and is black, having every sign of having passed through an extreme heat; when broken, the inside is of a light grey colour, mixed with black spots, and some shining particles, which the learned here have decided to be pyrites; and, therefore, it cannot be a lava, or they would have been decomposed."

The Abbate *Soldani*, Professor of Mathematics in the University of Siena, has published a more detailed account of the same phenomenon. He informs us, that an alarming cloud was seen in Tuscany, near Siena and Radacofani, proceeding from the north, about seven o'clock in the evening, discharging sparks like rockets, and throwing out smoke like a furnace, with explosions more resembling the discharge of cannon and musketry than thunder, and casting down ignited stones to the ground, while the lightning which issued from it was remarkably red, and less rapid than an ordinary flash. To persons in different situations, the cloud appeared to be of different shapes; and, though it remained suspended for a considerable time, its fire and smoke were visible in every direction. Its altitude, from a combination of cirumstances, was judged to be much above the common region of the clouds. One of the stones, which was of an irregular figure, weighed five pounds and a half, was black on the outside, as if suffused with smoke, and seems, internally, to be composed of matter of the colour of ashes, and in which were perceived small specks of metal, as of gold and silver. Besides this, about nineteen others were shown to Soldani, and all of them characterized by a black and glazed outer surface, by their resistance to acids, and by a degree of hardness which permitted them not to be scratched with the point of a penknife.

Signor *Montauli*, who observed the cloud as he happened to be travelling, described it as appearing much above the elevation of ordinary clouds, as wrapt in smoke and flame, and as gradually becoming white, without being visibly affected by the sun's rays, which beamed full on its lower portions. In the heart of it he could discern, as it were, the basin of a fiery furnace, with a rotatory motion. This curious observer likewise gives an account of a stone, which, he was assured, dropped from the cloud, at a farmer's feet, and was dug out of the ground into which it had penetrated. It was about five inches long, and four broad, nearly square, and smooth, black on the surface, as if singed, but, within, like a sand-stone, with various small particles of iron, and bright metallic stars. Most of the others which he examined were of a rudely trianglar shape, and some so small as not to weigh more than an ounce.

The ladies at Cozone, about twenty miles from Siena, saw a number of them come down with a great noise, in a neighbouring meadow; and one of them, which was soon after taken up by a young woman, burned her hand; another burned a peasant's hat; a third struck off a branch from a mulberry-tree; and a fourth very nearly hit a girl who was tending a flock of sheep. At Cozone, however, the stones were of a small size, and accompanied with the fall of sand; thus intimating a close connection between meteorites and showers of sand.

The specific gravity of the Siena stones was found to be about 3 3, or 3 4; and one of them, treated by Mr. Howard, as particularly detailed in the 92d vol. of the *Philosophical Transactions*. yielded,

Silica, ...	46 66
Magnesia, ...	22.67
Iron, ...	34.67
Nickel	2
	106

A pretty entire specimen occurs in Mr. Ferguson's collection.

The preceding case affords a striking example of the different manner in which we regard a phenomenon by itself, and the very same phenomenon, when we consider it in connection with others. The naturalits of Siena, aware that the stones had fallen after one of the most violent tempests, and on the day immediately subsequent to one of the most formidable eruptions of Vesuvius, were inclined to view it as electrical or volcanic; and Soldani stood almost single in the opinion, that the appearance was independent of the eruption. But they who now contemplate the same fact in its relation with so many others, who know that the Siena stones present both the same physical characters, and the same chemical results with others which are ascertained to have fallen in different parts of the world, when not a breeze or a cloud interrupted the serenity of the weather, are decidedly convinced that it has no reference to any volcanic eruption, or to any ordinary storm.

April 13, 1795. Stones fell in Ceylon. *Beck*.

The circumstances attending the fall of the Yorkshire stone are thus detailed by Major *Topham:*

" The man, who, by some fortuitous circumstance, happens to possess any extraordinary curiosity, has a very troublesome companion. It was my good fortune to tumble into this predicament by a stone falling near my house in the country: and though I have been called upon, both publicly and privately, for a thousand accounts, and have answered innumerable inquiries, I was resolved to consign the stone in question to some public museum, and to deliver with it the most accurate account I was able to take from living witnesses on the spot, as I was at that time engaged on business in London. The stone, therefore, will no longer ' blush unseen,' but be subject to be examined by every philosopher in the united kingdom, who may choose to visit the *Museum of Mr. Sowerby*....

" Having premised thus much, I shall proceed to state what circumstances attended the falling of the stone in question, which was witnessed by many people who could have no interest in fabricating a false account, and were far too simple to have done so. What is most singular is, that it should have been so well attested, because, on the high wolds of Yorkshire, thousands of stones might have fallen, and there might not have been even a solitary shepherd, or his more solitary dog, to have witnessed the occurrence.

" It was on Sunday, about three o'clock, the 13th of December, in the year 1795, that the stone in question fell within two fields of my house. The weather was misty, and, at times, inclining to rain; and though there was some thunder and lightning at a distance, it was not till the falling of the stone that the explosion took place, which alarmed the surrounding country, and which created so distinctly the sensation that something very singular had happened.

" When the stone fell, a shepherd of mine, who was returning from his sheep, was about 150 yards from the spot; George Sawden, a carpenter, was passing within 60 yards; and John Shipley, one of my farming servants, was so near the spot where it fell, that he was struck very forcibly by some of the mud and earth raised by the stone dashing into the earth, which it penetrated to the depth of twelve inches, and seven afterwards into the chalk rock, making in all a depth of nineteen inches from the surface.

" While the stone was passing through the air—which it did in a north-east direction from the sea coast—numbers of persons distinguished a body passing through the clouds, though not able to ascertain what it was; and two sons of the clergyman of Wold Newton (a village near me) saw it pass so distinctly by them, that they ran up immediately to my house, to know if any thing extraordinary had happened.

" In the different villages over which the stone took its direction, various were the people who heard the noise of something passing through the air, accurately and distinctly, though they could not imagine what was the cause of it; and in many of the provincial newspapers, these accounts were published at the time from different persons.

" In fact, no circumstance of the kind had ever more concurrent testimonies; and the appearance of the stone itself, while it resembles in composition those which are supposed to have fallen in various other parts of the world, has no counterpart or resemblance in the natural stones of the country.

" The stone, in its fall, excavated a place of the depth before mentioned, and of something more than a yard in diameter. It had fixed itself so strongly in the chalk rock, that it required some labour to dig it out.

" On being brought home, it was weighed; and the exact weight, at the time, was 56 pounds; which has been diminished in a small degree at present, by different pieces being taken from it as presents to different *literati* of the country. All the three witnesses who saw it fall, agree perfectly in this account of the manner of its fall, and that they saw a dark body passing through the air, and ultimately strike into the ground; and though, from their situation and characters in life, they could have no possible object in detailing a false account of this transaction, I felt so desirous of giving this matter every degree of authenticity, that, as a magistrate, I took their accounts upon oath, immediately on my return into the country. I saw no reason to doubt any of their evidence, after the most minute investigation of it."

Of a hundred and sixty-two parts of the composition of the Yorkshire stone, Mr. Howard found,

Silica, ...	75
Magnesia, . . .	37
Oxide of iron, .	48
Oxide of nickel, .	2
	162

M. de Drée, we may add, found it to correspond exactly, in aspect and character, with the meteoric fragments from Benares and Villefranche, of which mention will be made in the sequel.

January 4, 1796. Stones fell near Belaia-Ferkua, in Russia. *Gilb. An.*—February 19, 1790 The ensuing relation is extracted from Mr. Southey's *Letters from Spain and Portugal.*

"A phenomenon has occurred here within these few days, which we sometimes find mentioned in history, and always disbelieve. I shall make no comment on the account, but give you an authentic copy of the deposition of the witnesses before the magistrates.

"Elias Antonio, ordinary judge of the term of Evorah Monte, and inhabitant of the parish of Friexo, in the Herdade of Gayes, says, that, on the 19th day of February, (1796.) between one and two o'clock in the afternoon, he heard two reports, similar to those of the explosion of mines; after which he perceived a great rumbling noise, which lasted about two minutes. Looking up to the horizon, it was not obscured, neither was there any cloud or appearance from which he could conjecture the sound to have proceeded. He recollects, likewise, that the rumbling ran from north to east, the day being clear and serene.

"Gregorio Calado, labourer in the Herdade of Pazo, and term of Redondo, says, that he heard the abovementioned sound, and that a little while after, one of his servants, called Jose Fialho, brought him a stone of the colour of lead, weighing ten pounds, and irregular in its figure, which stone the said Jose Fialho had found in a meer of the Herdade called Pasquinha, in the term of Evorah Monte; for after the two reports and the rumbling sound, he heard some heavy body fall near him, and found this stone sunk in the ground, still warm, and the ground freshly moved. Four boys who were in the same part affirmed the same."

The evidence here adduced is not very circumstantial; yet, when taken in connection with similar cases, it tends to corroborate the general fact.

March 8 1796. After the fall of a fire-ball in Lusatia, there was found a viscid substance, having the consistency, colour, and odour of a brown varnish. Chladni, who procured a small portion of it, in a very dried state, conceived that it was principally composed of sulphur and carbon.

March 12, 1798 Concerning the stone which is reported to have fallen near Villefranche, in the department of the Rhône, we are presented with a great variety of details; but we shall notice only a few of the most important. When it was transmitted to M. Sage, Member of the National Institute, and Professor of the First School of Mines, he hastily considered it as only a pyritous and magnetical ore of iron, although it bore no resemblance to any known species of ore of that metal, since it contained nickel, silica, magnesia, and native iron, which, when the stone was polished, shone like steel. It was of an ash-grey colour, granulated, and speckled with grey shining metallic points. Its surface was covered on one side, with a dingy black enamel, about a third of a line in thickness; and it acted very powerfully on the magnetic needle. When the Senator *Chasset* sent it to M. Sage, it was accompanied with a historical notice of similar import with that which M. *Lelièvre* of Villefranche, who saw and described the phenomenon on the spot, had already communicated.

At six o'clock in the evening a round body, which diffused the most vivid light, was observed in the vicinity of Villefranche, moving westward and producing a hissing noise, like that of a bomb which traverses the air. This luminous body, which was seen at the same time at Lyons, and on Mont Cenis, marked its passage by a red track of fire, and exploded when about 200 toises from the earth, producing a loud report, and a commotion in the neighbourhood. One of the flaming fragments fell on the vineyard of Pierre Crepier, an inhabitant of Salés, making in the earth an opening of about twenty inches in depth, and eighteen in width. The analysis of Messsrs. Vauquelin and Howard first prompted M. Sage to examine this fragment and its history with more critical accuracy, and, finally, to renounce his scepticism with regard to the existence of meteoric concretions.

An account of the same meteor was published in the *Journal de Physique*, for Floreal, year 11, by *M. de Drée*, who visited the spot in 1802. From his minute and deliberate investigation, it appears, that, at the time above specified, a luminous and extraordinary globe, in the eastern quarter of the heavens, had scarcely arrested the attention of the inhabitants of Salés, and the adjacent villages, when its rapid approach, accompanied by a terrible whizzing noise, like that of an irregular hollow body, traversing the atmosphere with unusual velocity, inspired the whole commune with alarm, especially when they observed it passing over their heads, at an inconsiderable elevation, leaving behind it a long train of light, and emitting, with an almost unceasing crackling, small bright flames, like little stars. Its fall was remarked by three labourers, at the distance of only fifty paces. Montillard, one of the three, a young man, who happened to be next the falling body, was struck with terror, and threw down his coat and bundle of sticks, that he might run the faster. The other two, Chardon and Lapoces, fled, with equal precipitation, to Salés, where the alarm had become general. These three witnesses attest the astonishing rapidity of the meteor's motion, and the hissing which proceeded from the spot where it fell. Crepier, who happened to be at home, was so much terrified with the noise of its fall, within twenty yards of his house, that he locked himself up with his family, first in his cellar, and then in his private apartment, whence he ventured not to stir till next morning, when he was called to join Chardon, Lapoces, M. Brandel, and many others who had repaired to the precise spot where they had seen the fire-ball enter into the earth; and there, at the bottom of a wide aperture, eighteen inches deep, including the whole thickness of the mould, they found a large black mass, of an irregularly ovoid form, having some resemblance to a calf's head, completely incrusted with a black varnish, cracked in several places, and smelling of gun-powder. It was first of all brought to Crepier's house, and very closely examined: on breaking it, however, and observing nothing but stone, indifference succeeded to the curiosity of the observers; and they coolly attributed its appearance to causes more or less supernatural.

The simplicity of most of the accounts, their perfect agreement in every important point, and the number and integrity of the witnesses, removed all doubt and suspicion from the mind of M. de Drée.

The weight of the Villefranche stone, before it was broken, was about twenty pounds. Its black, vitrified, and opaque surface, gave fire with steel. Within, it was hard, earthy, of the colour of ashes, of a granulated texture presenting different substances scattered through it, viz. iron, in grains, from the smallest visible size to a line, or even more, in diameter, somewhat malleable, but harder and whiter than forged iron, white pyrites, both lamellar and granular, and approaching, in colour, to nickel, some grey globules, which seemed to present the characters of trap, and a very few and minute particles of steatite, inclining to an olive hue. On account of its heterogeneous composition, its specific gravity could not be easily ascertained. One hundred parts of the mass gave, according to Vauquelin,

Silica, . . .	46
Oxyd of iron, . .	38
Magnesia, . .	15
Nickel, . . .	2
Lime, . . .	2
	103

The excess of this result was ascribed to the absorption of oxygen, by the native iron, during the process.

December 19, 1798. About eight o'clock in the evening, a very luminous meteor, in the form of a large globe of fire, and accompanied by a loud thundering noise, was observed in the heavens by the inhabitants of Benares, and the parts adjacent. It was said to have discharged a number of stones near Krakhut, a village on the north side of the river Goomty, about fourteen miles from Benares. This meteor appeared in the western quarter of the hemisphere, and was visible only for a short time, to several Europeans, as well as natives, in different parts of the country. In the neighbourhood of Juanpoor, about twelve miles from the spot where the stones fell, it was distinctly perceived by various European ladies and gentlemen, who described it as a large ball of fire, accompanied by a rolling noise, which they compared to bad platoon firing. Mr. Judge *Davis* observed the light to come into the room which he occupied, through the casement, and so strongly as to project shadows very distinctly on a dark-coloured carpet.

When intelligence of the event reached Benares, Mr. Davis dispatched a judicious person to make the requisite inquiries. The natives, on being interrogated, mentioned, that they had either broken to pieces, or given to the collector and others, all the stones which they had gathered, but that others might still be found in the fields, by observing where the earth appeared to be recently turned up. Four were accordingly procured and brought to Mr. *Davis*. They had sunk about six inches deep into fields, which seemed to have been freshly watered, and about the distance of a hundred yards from one another. The person deputed to obtain information, was likewise told by the inhabitants of the village, that, about eight o'clock in the evening, when they had retired to their dwellings, they observed a very brilliant light, proceeding as from the sky, accompanied by a loud peal of thunder, which was immediately followed by the noise of heavy bodies falling in the neighbourhood. Uncertain whether some of their deities might not be concerned in this occurrence, they did not venture out till next morning, when the first circumstance which attracted their attention was the broken appearence of the surface of the ground: and further investigation corroborated these particulars. Mr. M'Lane, a gentleman who resided hard by Krak-hut, gave Mr. Howard part of a stone, which had been brought to him by the watchman who was on duty at his house. This, he said, had fallen through the top of his hut, which was close by, and buried itself several inches in the floor, which was of hardened earth. At the time that this meteor appeared, the sky was perfectly serene, and not a cloud had been seen since the 11th of the month, nor had any been observed for many days after.

"Of these stones," says Mr. Howard, "I have seen eight, nearly perfect, besides parts of several others, which had been broken by the possessors, to distribute among their friends. The form of the more perfect ones appeared to be that of an irregular cube, rounded off at the edges; but the angles were to be observed on most of them. They were of various sizes, from about three to upwards of four inches in their largest diameter; one of them, measuring four inches and a quarter, weighed two pounds twelve ounces. In appearance they were exactly similar: externally, they were covered with a hard black coat, or incrustation, which, in some parts, had the appearance of varnish, or bitumen; and on most of them were fractures, which, from their being covered with matter similar to that of the coat, seemed to have been made in the fall, by the stones striking against each other, and to have passed through some medium, probably an intense heat, previous to their reaching the earth. Internally, they consisted of a number of small spherical bodies of a slate colour, embedded in a whitish gritty substance, interspersed with bright shining spiculæ, of a metallic or pyritical nature. The spherical bodies were much harder than the rest of the stone: the white gritty part readily crumbled, on being rubbed with a hard body; and on being broken, a quantity attached itself to the magnet, but more particularly the outside coat or crust, which appeared almost wholly attractable by it.

"It is well known there are no volcanoes on the continent of India; and, as far as I can learn, no stones have been met with in the earth in that part of the world, which bear the smallest resemblance to those above described."

The history of the Benares meteor, then, speaks too distinctly for itself to stand in need of commentary.

April 5, 1799. Stones fell at Batonrouge, on the Mississippi. *Belfast Chronicle of the War.*

April 5, 1800. At night, a body wholly luminous was seen to move over a portion of America with prodigious velocity. Its apparent size was that of a large house seventy feet long, and its elevation above the surface of the earth about 200 yards. It diffused a light little inferior to that of the sun; and those who saw it perceived a considerable degree of heat, but no electrical sensation. Immediately after it disappeared in the north-west, with a violent rushing noise, which in a few seconds was followed by a tremenduous crash, and a very sensible vibration of the earth. Search being afterwards made in the place where the burning body fell, every vegetable was found burnt, or greatly scorched, and a considerable portion of the earth's surface broken up.

"We have to lament," remarks Mr. Howard, "that the authors of this account did not search deeper than the surface of the ground. Such an immense body, though moving in a horizontal direction, could not but be buried to a considerable depth. Should it have been more than the semblance of a body of a peculiar nature, the lapse of ages may perhaps effect what has now been neglected, and its magnitude and solitary situation become the astonishment of future philosophers." *Philos. Mag.*

1801. M. *Bory de St. Vincent*, the ingenious author of *Voyage dans les quatres principales Isles des Mers d'Afrique*, relates, (tom. iii. p. 253,) that in consequence of particular instructions from M. Hubert, he had, when on the Isle aux Tonneliers, made diligent search for the fragments of a stone which had been broken, and employed in the construction of a wall. Of these fragments he discovered three; one about the size of a melon, but too fast locked in the plaster to be detached, and the other two about the size of an orange each, and which were easily separated. They all evidently belonged to the same mass, and, though their fracture had become rusty, one side of their external surface exhibited, like certain lavas, a dark and polished tint, while their identity with stones reputed atmospheric seemed to leave no doubt of their origin. In regard to their history, M. *Descombes* informed the author, that some time before, probably in the year 1801, the ladies of the district were walking on the quay during a beautiful moonlight night, when all of a sudden they perceived a luminous cloud advancing from the west, and exploding with a very loud noise like the report of a cannon, but much more hollow, disclosing at the same time a beautiful ball of fire, in appearance perfectly spherical, and about a foot in diameter. When it broke from the cloud in which it had been conveyed, it was supposed to be half a league from the shore, to which it tended in a uniformly slanting direction, till it seemed to fall on the Isle aux Tonneliers. Several persons in the island of Bourbon affirmed, that on the same day, and at the same hour, they observed a luminous point in the air which, from the path of its motion, could be no other than this globe of fire.

March 5 and 6, 1803. A shower of red snow fell at Pezzo, at the extremity of the Valle Camonica. It was preceded by a violent wind on the 5th. *Journal de Physique*, 1804.

April 26, 1803. The history of the extraordinary shower of stones at L'Aigle, in Normandy, first appeared in the ensuing artless communication from M. *Marais*, resident in that place, to his friend at Paris.

"*At L'Aigle, the* 13*th Floreal, year* 11.

"An astonishing miracle has just occurred in our district. Here it is, without alteration, addition, or diminution. It is certain that it is the truth itself.

"On Friday last, 6th Floreal, between one and two o'clock in the afternoon, we were roused by a murmuring noise like thunder. On going out, we were surprized to see the sky pretty clear, with the exception of some small clouds. We took it for the noise of a carriage, or of fire in the neighbourhood. We were then in the meadow, to examine whence the noise proceeded, when we observed all the inhabitants of Pont de Pierre at their windows, and in gardens, inquiring concerning a cloud, which passed in the direction of from south to north, and from which the noise issued, although that cloud presented nothing extraordinary in its appearance. But great was our astonishment when we learned, that many and large stones had fallen from it, some of them weighing ten, eleven, and even seventeen pounds, in the space comprized between the house of the Buat family (half a league north north-east of l'Aigle) and Glos, passing by St. Nicholas, St. Pierre, &c. which struck us at first as a fable, but which was afterwards found to be true.

"The following is the explanation given of this extraordinary event by all who witnessed it.

"They heard a noise like that of a cannon, then a double report still louder than the preceding, followed by a rumbling noise which lasted about ten minutes, the same which we also heard, accompanied with hissings caused by these stones, which were counteracted in their fall by the different currents of air, which is very natural in the case of such a sudden expansion. Nothing more was heard; but it is remarkable, that previously to the explosion, the domestic fowls were alarmed, and the cows bellowed in an unusual manner. All the country folks were much dismayed, especially the women, who believed that the end of the world was at hand. A labouring man at La Sapée fell prostrate on the ground, exclaiming, 'Good God! is it possible that thou canst make me perish thus? Pardon, I beseech thee, all the faults that I have committed.' The most trifling objects, in fact, might create alarm; for it is not improbable that history offers no example of such a shower of stones as this. The piece which I send was detached from a large one weighing eleven pounds, which was found between the house of the Buats and Le Fertey. It is said that a collector of curiosities purchased one of seventeen pounds weight, that he might send it to Paris. Every body in this country is desirous of possessing a whole stone, or a fragment of one, as an object of curiosity. The largest were darted with such violence, that they entered at least a foot into the earth. They are black on the outside, and greyish, as you see, within, seeming to contain some pieces of metal and nitre. If you are the first to know of what ingredients they are composed, you will inform us. One fell near M. Bois de la Ville, who lives hard by Glos. He was much afraid, and took shelter under a tree. He has found a great number of them of different sizes in his court-yard, his wheat fields, &c. without reckoning all those which the peasants have found elsewhere. Numberless stories, more or less absurd, have been circulated among the people. You know that our country is fertile in such tales. Cousin Moutardier sends one of these stones to Mademoiselle Hebert; and he is not less eager than we are to know how these substances can be compressed and petrified in the air. Do try to explain the process.

"The person who gave me the largest stone which I send to you, went to take it at the moment that it fell, but it was so hot that it burned him. Several of his neighbours shared the same fate in attempting to lift it.

"The elder Buat has just arrived, and desires us to add, that a fire-ball was observed to hover over the meadow. Perhaps it was wild-fire."

At the sitting of the Institute on the 9th of May, Fourcroy read a letter addressed to Vauquelin, from the town of L'Aigle, containing, among other details, the following:

On the 26th of April, about one o'clock, P. M. the sky being almost serene, a rolling noise like that of thunder was heard. It seemed to proceed from a single cloud which was on the horizon, and which the inhabitants beheld with uneasiness, when, to their great surprise and terror, explosions like the reports of cannon, sometimes single and sometimes double, were heard, along with a violent hissing,—phenomena which struck terror even into domestic animals; for the cows bellowed, and the poultry fled to a place of shelter. This noise was succeeded by the fall of a great number of stones of different sizes, weighing ten, eleven, and even seventeen pounds. The largest entered the earth to the depth of a foot. Several of these fell into the court-yard of M. Bois-de-la-Ville, and one of them very near him. Many curious persons collected some of them; and Fourcroy laid before the Institute one of the fragments, which, when compared with that of the Villefranche specimen, presented at the meeting by Pictet, greatly resembled it in every point, exhibiting the same colour, texture, and black crust; in a word, the fragments could not be distinguished from each other but by the size.

Lamarck then reported that he had received several letters, apprizing him of a fire-ball which had been seen to pass from east to west with great velocity on the same day, and at the same hour, at which the event alluded to took place. It was added, that this meteor had been seen at sea before it reached the continent.

But we pass to the substance of M. Biot's letter, addressed to the minister of the interior, and published in the *Journal des Debats*. This gentleman, who is advantageously known over Europe for his scientific attainments, was deputed by government to repair to the spot, and collect all the authentic facts. The contents of his letter have been since expanded into the form of a memoir, which manifests the caution and judgment that guided his inquiries.

M. Biot left Paris on the 25th of June, and, in place of proceeding directly to L'Aigle, went first to Alençon, which lies fifteen leagues to the west south-west of it. On his way, he was informed that a globe of fire had been observed moving towards the north, and that its appearance was followed by a violent explosion. From Alençon he journeyed through various villages to L'Aigle, being directed in his progress by the accounts of the inhabitants, who had all heard the explosion on the day and at the hour specified; and almost all the residents of twenty hamlets declared, that they were eye-witnesses of a dreadful shower of stones which was darted from the meteor. The summary of the evidence which M. Biot collected, may be thus expressed.

About one o'clock, P. M. the weather being serene, there was observed from Caen, Pont-d'Audemer, and the environs of Alençon, Falaise and Verneuil, a fiery globe of uncommon splendour, and which moved in the atmosphere with great rapidity. Some moments after, there was heard at L'Aigle, and for thirty leagues round in every direction, a violent explosion, which lasted five or six minutes. Three or four reports, like those of cannon, were followed by a kind of discharge, which resembled the firing of musketry; after which, there was heard a dreadful rumbling, like the beating of a drum. The air was calm, and the sky serene, with the exception of a few clouds, such as are commonly observed at that season. The noise proceeded from a small cloud which had a rectangular form, the largest side being in a direction from east to west. It appeared motionless all the time that the phenomenon lasted; but the vapours of which it was composed were projected momentarily from different sides, by the effect of the successive explosions. This cloud was about half a league to the north north-west of the town of L'Aigle, and at a great elevation in the atmosphere; for the inhabitants of two hamlets, a league distant from each other, saw it at the same time above their heads. In the whole district over which this cloud was suspended, there was heard a hissing noise, like that of a stone discharged from a sling; and a great many mineral masses, exactly similar to those distinguished by the name of *meteor-stones*, were seen to fall.

The portion of country in which these masses were projected, forms an elliptical extent of nearly two leagues and a half in length, and nearly one in breadth, the greatest dimension being in a direction from south east to north-west, forming a declination of about 22 degrees. This direction, which the meteor must have followed, is exactly that of the magnetic meridian, which is a remarkable result. The greatest of the stones fell at the south-eastern extremity of the large axis of the ellipse, the middle-sized in the centre, and the smallest at the north-western extremity. Hence it appears that the largest fell first, as might be naturally supposed. The largest of all those which fell weighed $17\frac{1}{2}$ lb. and the smallest which was subjected to M. Biot's inspection, only a thousandth part of that weight, or two French *gros*.

As we cannot make room for an analysis of M. Biot's more extended communication, we shall be contented to select only two facts.

The vicar of St. Michel declared, that he observed one of the stones fall with a hissing noise at the feet of his niece, in the court-yard of his parsonage, and that it rebounded more than a foot from the pavement. He instantly requested his niece to fetch it; but, as she was too much alarmed, a woman, who happened also to be on the spot, took it up, and it was found in every respect to resemble the others.

As one Piche, a wire-manufacturer in the village of Aunées, was working with his men in the open air, a stone grazed his arm, and fell at his feet; but it was so hot, that, on attempting to take it up, he instantly let it fall again.

He who compares the various accounts of the L'Aigle meteor with a critical eye, may, no doubt, detect some apparent contradictions, but which, on reflection, will be found strictly conformable to truth. Thus, according to some, the meteor had a rapid motion, others believed it to be stationary: some saw a very luminous ball of fire, and others only an ordinary cloud. Spectators, in fact, viewed it in different positions with regard to its direction; for they who happened to be in the line of its progress would see it stationary, for the same reason that we fancy a ship under full sail to be motionless when we are placed in its wake, or when we view it from a harbour to which it is approaching in a straight line; they, on the other hand, who had a side view of it, would reckon its motion the more rapid as their position approached to a right angle with the line of its passage, while they who saw it from behind, as the inhabitants of L'Aigle, would perceive only the cloud of vapour which it left in its train, and which, in the shade, would figure like a blazing tail, in the same manner as the smoke of a volcano appears black during the day and red at night; lastly, they who were placed in front of the meteor would reckon it stationary, but brilliant and cloudless.

It deserves to be remarked, that most of the stones, for some days after their descent, were very friable; that they gradually acquired hardness; and that, after they had lost the sulphureous odour on their surface, they still retained it in their substance, as was discovered by breaking them. Professor Sage submitted them to several comparative trials with those of Villefranche; and, although the L'Aigle specimens presented some globules of the size of a small coriander seed, of a darker grey than the mass, and not attractable by the magnet, yet, in respect of granular texture and general aspect, the coincidence was so striking as to lead one to suppose that they were all parts of the same mass. According to Fourcroy, who was also furnished with documents and specimens, most of the L'Aigle stones were irregular, polygonal, often cuboid, sometimes sub-cuneiform, and exceedingly various in their diameter and weight. They were all, he observes, covered with a black gravelly crust, consisting of a fused matter, and filled with small agglutinated grains of iron. The greater part of them were broken at the corners, either by their shock against one another, or by falling on hard bodies. The interior parts resembled those of all the meteorites analysed by Messrs. Howard and Vauquelin, being grey, somewhat varied in their shadings, granulated, and as it were scaly, split in many parts, and filled with brilliant metallic points, exactly of the same aspect as those of other stones of the like kind. Of the two specimens which M. Biot presented to Patrin, one was less compact, and of a lighter grey than the other, and exhibited, besides, small patches of a rust colour. When immersed in water, it gave a hissing sound like the humming of a fly when held by one wing. As it began to dry, it was observed to be marked by curvilinear and parallel layers. The more compact specimen, when moistened, presented no such appearances, but assumed the aspect of a grey porphyry, with a base of trap, mottled with small white spots, and speckled with metallic points.

Vauquelin's analysis of these stones yielded

Silica	53
Lime	1
Magnesia	9
Oxyd of iron	36
Nickel	3
Sulphur	2
	104

The addition of four per cent. may be attributed to the oxidation of the metals produced by the analysis. Thenard reports,

Silica	46
Magnesia	10
Oxyd of iron	45
Nickel	2
Sulphur	5
	108

M. Laugier moreover detected a small proportion of chrome. M. Lambotin and others collected specimens of this extraordinary shower of stones, and distributed them among the curious. We have seen two fine samples, one of them nearly entire, in Mr. Ferguson's collection, which we have already repeatedly quoted.

Previously to the memorable explosion above recited, no meteorites had been found in the hands of the inhabitants of this district of country, nor in the mineralogical collections of the department, nor had the slightest intimation of them occurred in the geological documents of the environs of L'Aigle. We may also note, that the forges and mines of the district in question produce nothing similar in the form of dross or ore; that the soil exhibits no traces of volcanoes; and that immediately consequent on the appearance of the meteor, a determined space of ground was strewed with stones of a peculiar character, and accompanied with circumstances which could not formerly have escaped observation. Again, nearly all the inhabitants of 20 hamlets, dispersed over the circumscribed space, declare that they were eye-witnesses of a terrible fall of stones projected from the meteor. The young, the old, and those in the prime of life, individuals of both sexes, simple peasants dwelling at a distance from one another, sagacious and rational workmen, respectable ecclesiastics, young soldiers devoid of fear, persons, in short, of various manners, professions, and opinions, and united by no common ties, all concur in attesting a fact, which contributed neither directly nor indirectly to promote their own interest; and they all assign the manifestation of this fact to the same day and the same hour. They moreover point to obvious and existing consequences of the fall of stony masses; and they aver, in terms incapable of ambiguity or misconstruction, that they really saw these masses roll down on roofs, break branches of trees, rebound from the pavement, and produce smoke when they lighted on the soil. These assertions, and their corroborative indications, refer to a portion of territory which has been accurately defined, and beyond whose precincts not a single corresponding mass has been found, nor a single individual who alleges that he saw a stone fall. Such incontrovertible evidence, then, will preclude the necessity of dilating on cases of inferior notoriety, and to which we are induced to advert, principally for the purpose of completing our chronological catalogue, and deducing the known series of an occurrence, the solution of which is still somewhat problematical.

July 4, 1803. A ball of fire struck the White Bull Inn, at East Norton, by which the chimney was thrown down, the roof partly torn off, the windows shattered to atoms, and the dairy, pantry, &c. converted into a heap of ruins. It appeared like a luminous ball of considerable magnitude, and, on coming in contact with the house, exploded with a great noise and a very oppressive sulphureous smell. Some fragments of it were found near the spot, and were subjected to chemical analysis by a gentleman in the neighbourhood, who found them to consist of one-half siliceous clay, thirty-five parts of oxidated iron, twelve of magnesia, and a small portion of nickel, with some sulphur. The surface was dark and varnished, as if in a state of fusion, and bearing numerous globules of a whitish metal, containing sulphur and nickel. From some indentures on the surface, it appeared probable that the ball was soft when it descended. Where the fragments fell, the herbage was burnt up. The meteor's motion in the air was very rapid, and apparently parallel to the horizon. *Liter. Journal.*

October 5, 1803. Stones fell near Avignon. *Bibl. Britan.*

December 13, 1803. The inhabitants of the village of St. Nicholas, in Bavaria, were alarmed between eleven and twelve o'clock, noon, by a noise which resembled the report of several cannons. A peasant, who went out of his house to see what was the matter, observed the sky to become dark and gloomy, heard a singular hissing in the air, and perceived something fall on a barn with a loud noise. On entering the barn, he found a stone which had broken the rafters by its fall, was still warm, smelled of sulphur, and weighed three pounds and a quarter. It was covered by a thin, blackish, and apparently bituminous incrustation. Its substance was of an ash-grey colour, earthy, and resembling hardened clay, but without odour. It was found to contain small shining particles of native iron, small bright grains of martial pyrites, which yielded a black powder when pounded, hard and very bright flattened masses, of a black and dark-brown hue, some minute grains of a cubical form, and small yellowish transparent laminæ, with glass glance, having the appearance, but not the hardness, of quartz. Yellowish, white, and metallic points, probably native nickel, were discovered by the microscope. The chemical analysis of 10,000 grains of this specimen, gave

Iron, in the metallic state,	1800
Brown oxyd of do.	2540
Regulus of nickel,	1350
Magnesia,	3250
Silex,	1000
Supposed sulphur,	60
	10,000

Journal de Physique, Gilb. An. Voight's Mag.

April 5, 1804. Three men at work in a field at Possil, about three miles north from Glasgow, were alarmed by a singular noise, which seemed to proceed from the south-east to the north-west, and continued, as they supposed, for about two minutes. They compared it, at first, to four discharges of cannon, afterwards to the sound of a bell, or rather of a gong, with a violently whizzing noise; and, lastly, they heard a sound, as if some hard body very forcibly struck the surface of the earth. At the same time, sixteen men who were at work in the Possil stone quarry, thirty feet under the surface of the soil, heard a noise like the discharge of artillery, and then like the sound of hard substances hurling downwards over stones, and lasting, in the whole, for about the space of a minute. The overseer of the quarry, and a man who was on a tree, described the noise as if continuing about two minutes, apparently beginning in the west, and passing round by the south, towards the east, at first like the firing of three or four cannons, at the distance of a mile and a half to the west of the quarry, and terminating in a violent rushing, or whizzing. Along with these persons, there were two boys, one of ten, and the other of four years of age, and a dog, which, on hearing the noise, ran home, seemingly in great terror. The overseer, too, was considerably alarmed by a misty commotion which he observed in the atmosphere. "Come down," exclaimed he, to the man on the tree, "I think there is some judgment coming upon us." The man had scarcely got on the ground, when something struck, with great force, in a drain, at the distance of about ninety yards, splashing mud and water for twenty feet round. The elder boy observed the appearance of smoke in the air, and something of a reddish colour, moving rapidly from the west, till it fell on the ground. A moment before the stroke on the earth was heard, the younger boy called out—"*Oh! sik a reek!*" (such a smoke,) alluding to the smoke which he saw near the place where the body fell on the ground. On running up to this spot, the overseer observed a hole in the bottom of the drain, which was filling with water, about six inches of it remaining still empty. At the bottom of this hole he felt something hard, which he could not move with his hand. The operation of the shovel and mattock revealed two pieces of stone, which had penetrated a few inches into the soft sandy rock, and eighteen inches below the bottom of the drain, the hole being about fifteen inches in diameter. He was not sensible of any particular heat in the water, or in the pieces of stone, nor of any uncommon smell in the latter, although he applied them to his nostrils. One of the pieces was about two inches long, the other about six inches long, four broad, and four thick, and blunted at the edges and end. The fractures of the two pieces exactly coincided; but he could not say whether their separation had been effected by the violence of the fall, or a stroke of the mattock. As he conceived them to be merely pieces of whinstone, they were, at first, neglected; but a careful search being made for them, some days after, the smallest fragment was soon found. The largest, however, having been used as a block in the quarry, and having fallen among rubbish, could not be discovered; but a fragment of it was found some days after The two recovered morsels, one of which is deposited in the Hunterian museum, in the university of Glasgow, formed the two extremes of the stone, and are characterized by the smooth black external coating, and the internal greyish aspect. The late Robert Crawfurd of Possil, Esq. and several of the professors of the university of Glasgow, were at pains to ascertain the preceding circumstances. Mr. Crawfurd remarked, that both the fragments had a fishy, fetid smell, when he first received them. The day on which the phenomenon took place was cold and cloudy; and the noise of the explosion was heard as far as Falkirk, which is about twenty-four miles to the east of Glasgow.

1804, or 1807. A stone fell near Dordrecht. *Van Beck-Calkoen.*

October 6, 1804. A violent explosion was heard, near Apt, in the department of Vaucluse, and for fifteen leagues round, accompanied by an extraordinary hissing, and the fall of a stone of about seven pounds weight. It was presented, by the minister of the interior, to the National Institute; and Vauquelin, who alludes to it in No. 144 of the *Annales de Chimie*, asserts, that all its physical characters, and the details of the judicial report concerning it, are in perfect unison with our present state of knowledge on the subject. It is, however, worthy of remark, that the detonation was preceded by no luminous meteor. Laugier reports, as the results of the chemical analysis of the stone,

Silica,	34
Magnesia,	14.5
Iron,	38.03
Nickel,	0.33
Manganese,	0.83
Sulphur,	9.
	96 69.

March 25, 1805. Stones fell near Doroninsk, at no great distance from the river Indoga, in the government of Irkutsch, in Siberia. *Gilb. An.*

June, 1805. Haïr Kougas Ingigian, author of a work, entitled *Eghang-Buzankian*, printed at Venice, in 1807, makes mention of several stones having fallen in one of the public squares of Constantinople, called *Etmeydany*. Haïr Mesrob Vartabete, an Armenian, conversant in chemistry, mineralogy, and in the physical and mathematical sciences in general, translated the passage which gives an account of this event, into French, for the perusal of M. Tonnelier; and the latter, in the Journal of Mines for February, 1808, briefly states, that the descent of the stones took place in broad day, and with great violence; that the people believed it to be the work of evil spirits; that the agents of police verified the fact; and that a guard of Janissaries was stationed on the spot, for three successive days and nights. The smell of sulphur which accompanied the fall, and the black and scorched crust of the pieces collected, scarcely permit us to doubt that they were genuine meteorites.

March 15, 1806. In the *Journal de Physique*, for June 1806, there is a short account of the fall of two *aërolites*, (for so they are termed in the report,) by Dr. Pages and M. Dhombres-Firmas, both members of the Academy of Ghent. The particulars are nearly as follow:—

At half-past five o'clock in the evening, the inhabitants of Alais, and the neighbouring parishes, heard two loud explosions, between which only a few seconds intervened, and which were both supposed to be the discharge of cannon. The rolling noise which succeeded, lasted ten or twelve minutes. Some drops of rain had fallen in the morning; the sky was clear at mid-day; but clouds occasionally obscured the sun in the afternoon, when the centigrade thermometer indicated a maximum of + 12.5. The heavens became more cloudy and dark after the detonations. The Sieurs Penarier, father and son, who were in the fields adjoining to the village of St. Etienne de L'Olm, about twelve kilometers from Alais, heard the two explosions, which were not preceded by lightning, and which they at first supposed to be the firing of cannon at St. Hippolyte-le-fort; but the rolling sound which succeeded, and which seemed to them to describe a curve in the heavens, from west to south, and from south to east, quickly undeceived them. As they looked more attentively at the clouds, an extraordinary hissing noise succeeded the rolling, and they distinctly perceived a blackish body proceeding from the clouds, obliquely advancing towards them from the north, and which, after passing over their heads, fell in a corn-field below the village, and broke in shivers, with a considerable noise. Accompanied by several of the alarmed villagers, they immediately went in quest of it, and found that it had pierced the soil, and broken into dispersed fragments against a rocky stratum, only small splinters, which were diluted by the rain that fell two days after, remaining in the hollow formed by the falling mass. From the respective weights of the fragments, it was supposed that that of the entire stone might be 4000 grammes. Its form, so far as could be inferred from the fragments, was irregular and angular; and it was black *internally* as well as on the surface, which last seemed to have undergone the action of fire.

There fell, at the same time, at Valence, a village near Alais, another stone, of a rudely cubical form, of the size of a child's head, and about four pounds weight. The persons who witnessed its descent, were Pierre Reboul, and son, Vincent Mazel, and Pierre Esperaudieu, servant to the mayor of Valence, who were labouring in the fields when the explosions and rolling noise mentioned above arrested their attention. According to their report, these noises were followed by another, resembling that of an iron pulley, by means of which a bucket is rapidly let down into a draw-well. On looking up, they perceived a black body moving from the north, in an oblique direction, which fell among them, about fifteen paces from Reboul. They all ran to the spot, and found it half buried in the earth, still hot, and split into three parts, which were again divided, as each was desirous of having a specimen.

The Alais stone, according to Thénard, had such a strong resemblance to coal, that they who found it attempted to burn it. Its specific gravity was 1940, consequently very inferior to that of other meteorites whose specific gravity has been ascertained. Its internal substance exhibited some yellow specks of martial pyrites, and a great many cubical points, slightly united to one another, and so friable that the least pressure reduced them to fragments of the size of grains of sand. It was destitute of savour, and insoluble in water. When heated in the open air, its black hue passed to a reddish yellow; but, when heated in close vessels, remained unchanged. Before the common blow-pipe, it was infusible, without addition; but, when mixed with borax, it readily melted, and communicated to that salt a greenish-yellow tinge. The same ingenious chemist states it component parts to be,

Silica,	21
Magnesia,	9
Oxyd of iron,	40
Nickel,	2.50
Manganese,	2
Sulphur,	3.5
Chrome,	1
Carbon,	2.5,

the remainder being estimated as water. Vauquelin again reports,

Silica,	30
Magnesia,	11
Iron,	38
Nickel,	2
Manganese,	2
Sulphur,	1
Chrome,	2.5
Carbon, a trace.	

and the virtual import of these analyses was attested by Monge, Fourcroy, and Berthollet.

May 17, 1806. As Mr. William Paice, of Basingstoke, Hants, was travelling with his cart, a few miles from home, he met a person, who inquired of him whether he had seen a stream of fire descend from the air, like a falling star, there having been some thunder just before. Mr. Paice had not observed it; but, going on a little farther, he found a large ball, or stone, which he took up, while yet hot, from the middle of the road, threw it into his cart, and brought it home. It had a metallic appearance, and weighed two pounds and a half. *Month. Mag.*

March 13, 1807. In the afternoon, the inhabitants of the Canton of Juchnow, in the government of Smolensko, were alarmed by an uncommonly loud noise, which they supposed to be thunder; and two peasants being out in the fields, perceived, at the distance of forty paces, a black stone, of considerable magnitude, falling to the earth, which it penetrated to a considerable depth beneath the snow. When dug up, it was found to be of an oblong quadrangular figure, of a blackish colour, resembling cast iron, and to weigh 160 pounds

A fragment of this mass is preserved in the imperial cabinet of Vienna. Its specific gravity was 3.7; and Klaproth notes its constituents thus,

Silica, ...	38

December 14, 1807. About half past six o'clock in the morning, the people to the north of Weston, in Connecticut, North America observed a fire-ball issuing from a very dark cloud. Its apparent diameter was equal to that of the half, or of two-thirds, of the moon; its light was vivid and sparkling, like that of incandescent iron, and it left behind it a pale and waving luminous train, of a conical form, and ten or twelve times as long as the diameter of its body, but which was soon extinguished. This meteor, of which the apparent motion was less rapid than that of most others, continued visible for half a minute, during which it exhibited three successive bounds, with a diminution of its lustre. About thirty or forty seconds after its extinction, there were heard, during three seconds, three very loud reports, like the firing of a four pounder at a little distance; and these were succeeded by a more prolonged and rolling noise. With the successive explosions, stones were darted in the environs of Weston, and even into the town itself. These stones were found in six different places, nearly in the line of the meteor's path, and from six to ten miles distant from one another. They fell in the presence of many witnesses, some plunging into soft soil, and others breaking into fragments against the rocks on which they happened to impinge. The most entire specimen weighed 35 lb., but a much larger was dashed in pieces against a rock of mica-slate; and, from the amount of fragments collected, it was estimated to have weighed 200 lb. At the moment of their fall, these stones were hot and friable; but they gradually became hard by exposure to the air. They had the black external crust of other meteorites, and the usual grey cinereous aspect within, with whitish-grey particles, of a rounded form, impacted in the mass, and a general granular texture, in which were observable, 1. Globules of the same nature with the stone, but presenting a more compact structure, a more even fracture, and, under a strong light, indications of a lamellar texture, with the appearance of felspar; 2. Grains of very white metallic iron; 3. Grains of oxyd of iron, of rust colour; and, 4. Shining yellow sulphuret of iron, disseminated in very minute grains. Their specific gravity varied from 3.3 to 3.6, and their analysis, as reported by Warden, yielded,

Such is a mere outline of the principal circumstances relative to the Weston phenomenon, for the more ample details of which we must refer our readers to an interesting memoir, inserted in the Medical Repository for 1807, the joint production of Messrs Silliman and Kingsley, and to another by Mr. Bowditch, published in the third volume of the American Academy of Arts and Sciences, and reprinted in the 28th volume of Nicholson's Journal.

March 5 and 6, 1808. A shower of red snow fell, during three nights, in Carniola, and over the whole surface of Carnia, Cadore, Belluno, and Feltri, to the height of five feet ten inches. The earth was previously covered with snow of a pure white, and the coloured variety was again succeeded by the common sort, the two kinds remaining perfectly distinct, even during liquefaction. When a portion of the red was melted, and the water evaporated, a little finely divided earth, of a rose hue, remained not attractable by the magnet, and consisting of silex, alumine, and oxyd of iron. The same phenomenon was observed at the same time, on the mountains of the Valteline, Brescia, and the Tyrol.

April 19, 1808. At one o'clock P. M. stones fell at Borgo San Domino, near Pieve di Cassignano, in the department of Taro, and in the neighbourhood of Parma and Placenza. Guidotti, who analyzed a specimen, found it to consist of,

Silica, . . .	50
Magnesia, . . .	11
Oxyd of iron, . .	39
Nickel, ...	2 50
Sulphur, . . .	4
	106.50

A specimen of this shower is preserved in the Vienna cabinet, a repository rich in the number of samples of this description of stones.

May 22, 1808. At six o'clock in the morning, a shower of stones occurred at Stannern, near Iglau, in Moravia, attended with the usual circumstances. These stones are described as of a whitish or bluish-grey, tender, friable, not magnetic, speckled with black points, containing very few visible metallic particles, except some prominent grains, not attractable by the magnet, and probably pyritical. The exterior crust resembled a black, or brown varnish, very glossy and vitreous, having the surface marked by minute folds or wrinkles. Their specific gravity was 3.19; and the result of their analysis by Vauquelin,

Silica, ...	50

Sulphur, a trace	
	101

Moser's report includes 2.5 of magnesia.

September 3, 1808. M. Reuss, counsellor of mines, has published a Memoir on the meteorites which fell, at half past three o'clock in the afternoon, near Lissa, in Bohemia: and from this document we have selected the following most material circumstances.

Four days after the event, the mayor of the district received an official report on the subject, as did afterwards M. Merkl, counsellor of the government, who communicated the contents to the Chancery. Lissa is a small town, situated four miles west north-west from Prague; and the district in which the stones fell is a plain, which extends southwards to the banks of the Elbe. The soil, in general, is a dry meagre sand, fit only for the culture of rye, and the rocks which it comprizes are of a ferruginous argillaceous sandstone. The field on which the meteorites alighted had been recently ploughed, and had for its basis a very open, sandy earth, into which, nevertheless, one of the stones sunk only to the depth of four inches. Another, which fell on an adjoining field, of a somewhat more compact and argillaceous texture, penetrated four or five inches. A third fell in a small pine forest, on a sandy soil, covered here and there with green turf, and left, in like manner, a mark of four or five inches deep. Though all its angles were more or less fractured, it weighed five pounds nine ounces and a half. The most intelligent people in the neighbourhood declared that they heard a violent detonation, like the discharge of many pieces of ordnance, followed by a noise like platoon firing, or a prolonged beating of drums, which lasted for twenty or twenty five minutes. The sky, which had been perfectly clear, became covered as with a thin gauze, through which the sun's rays easily penetrated; but nobody perceived lightning, nor any luminous meteor, nor felt any of that oppressive uneasiness, which frequently indicates an electrified atmosphere. Of the four masses which were collected, the actual descent of none through the air appears to have been distinctly witnessed; but some reapers, who took up one of them, at the moment that it struck the ground, felt it as cold as the surrounding stones; and none of them stained the fingers, or emitted any sulphureous odour. In other respects, they bore a manifest resemblance to many of those which we have described, being composed of mixed ingredients, of a pale cinereous grey colour, and granular texture, traversed in every direction by small veins and speckled with minute, disseminated globules. Their specific gravity is stated at 3.56, and Claproth found them to contain,

Silica,	43
Alumina,	1.25
Lime,	0.50
Magnesia	22
Iron,	29
Nickel,	0 50
Manganese,	0.25
Sulphur, a trace	
	96.50

All the iron contained in the specimen submitted to trial, appeared to be in the metallic state. The peculiarities attending this case are, detonation without any luminous meteor, the very moderate impetus of the falling bodies, and their want of sensible heat.

July 17, 1809. A stone, weighing six ounces, fell on board an American vessel, in Lat. 3 ° 65′ N. and Long. 70°,25′. W. *Medic. Repos. Biblioth. Britan.*

January 30, 1810. At two o'clock, P. M. a fall of meteorites occurred in Caswell county, North America. Their descent was visible for a considerable distance round; and two reports were distinctly heard at Hillsborough, thirty miles from the spot where the fall took place. One of the fragments, weighing a pound and three quarters, struck a tree near the place where some woodcutters were at work, but who ran home, without ever once looking behind them. Encouraged, however, by a woman, whose curiosity was superior to her fears, they returned with her, and found the stone, which was still hot. It is vaguely said to have been of a dark-brown colour, and porous. *Phil. Mag.* vol. xxxvi.

July, 1810. A letter from Futty-Ghur, in the East Indies, dated July 21st, presents us with the following imperfect, but curious, account of the phenomenon which we have been considering. "I open this letter to let you know of a very odd circumstance which happened a few days ago. viz.—A large ball of fire fell from the clouds, which has burned five villages, destroyed the crops, and some men and women. This happened near Shahabad, across the Ganges, about 30 miles northward from this place. I have heard nothing further about this but a vague report."

August 10, 1810. In this stage of our historical record, it will be proper to insert the ensuing letter from Maurice Crosbie Moore, Esq. to William Higgins, Esq.

"Sir.—I had the honour of receiving a letter, requesting from me the particulars respecting a meteoric stone that fell near my house, in the county of Tipperary, and which a short time ago I did myself the pleasure of presenting to the Dublin Society. The particulars are as follow:—Early last August, between eleven and twelve o'clock in the morning, I went from Moore's Fort to Limerick; the day was dark and sultry. I returned in a few days, and was immediately informed by my steward and butler, that a most wonderful phenomenon had occurred very soon after my departure; they produced the stone, and gave the following account of the occurrence:—There had been thunder; some workmen, who were laying lead along the gutters of my house, were suddenly astonished at hearing a whistling noise in the air; one said, 'The chimney is on fire;' another said, 'It proceeds from a swarm of bees in the air.' On looking up, they observed a small black cloud, very low, carried by a different current of air from the mass of clouds, from whence they imagined this stone to have proceeded; it flew with the greatest velocity over their heads, and fell in a field, about three hundred yards from the house: they saw it fall. It was immediately dug up, and taken into the steward's office, where it remained two hours cooling before it could be handled. This account I have had from many who were present, and agree in the one story. I saw, myself, the hole the stone made in the ground; it was not more than a foot in depth," &c.

This stone was not injured by the fall, and was of a somewhat cubical shape with the angles and edges of two sides rounded; the other two opposite sides exhibited a very uneven surface, occasioned by depressions and prominences, as if a part had been broken previous to the heat to which it must have been exposed before its fall. It weighed seven pounds and three quarters; and the entire surface was covered with a brownish-black thin crust, evidently the effect of fusion, by an intense and rapid heat. On inspection of its internal texture, there were distinguishable, 1. Dark-grey particles of malleable iron, without any regular shape, of unequal magnitude, numerously dispersed, and rendered bright when rubbed with a file; 2. Some very small bright particles of iron; 3. Particles of martial pyrites, of various colours, some being reddish-yellow, some yellowish-white, and a very few of a purplish tinge; 4. A very few round globules, about the size of mustard-seed, of a greyish-brown, readily yielding to the file, and seeming to contain no metallic matter. These several materials are cemented by a whitish-grey earthy substance, while minute yellowish-brown spots, very close to one another, and proceeding from oxyd of iron, are disseminated in the mass. According to Mr. Higgins, its specific gravity is 3670; and its analysis gave, in one instance,

Silica	48.25
Magnesia	9
Iron	39
Nickel	1.75
Sulphur	4
	102

and, in another,

Silica	46
Magnesia	12.25
Iron	42
Nickel	1.50
Sulphur	4
	105.75

the excess being attributable to the absorption of oxygen by the metallic bodies.

November 23, 1810. At half after one o'clock P. M. three stones fell in the commune of Charsonville, in the department of the Loiret, and neighbourhood of Orleans. Their fall was accompanied by a series of detonations which lasted some minutes, and which, along with the reverberations from the echoes, were heard as loud at Orleans, Montargis, Salbri, Vierzon, and Blois, as at the place where the stones fell, exciting alarm from the apprehension of the blowing up of a powder magazine. These stones were precipitated perpendicularly, and without the appearance of any light or ball of fire. One of them took the ground at Montelle, but was never discovered; and, of the other two, one fell at Villenoi, and the other at Moulin-Brûle, all which places are within the distance of a mile. One of the stones weighed about twenty pounds, and made a hole in the ground just large enough for its admission, in a perpendicular direction, driving up the earth to the height of eight or ten feet. It was taken out half an hour after, when it was still so hot that it could scarcely be held in the hand; and it had a strong smell of gunpowder, which it retained till it was quite cold. The second formed a similar hole, three feet deep, weighed forty pounds, and lay fourteen hours in the ground before it was extracted, when it was quite cool.

Both these stones were shapeless masses, irregularly rounded at the projections, contained rather more ferruginous globules than those of L'Aigle, and presented a lighter colour, when broken. They were quickly oxydated, very heavy, sufficiently hard to scratch glass, of difficult frangibility, and characterized by an irregular and very fine-grained fracture. The external crust was the fourth part of a line in thickness, and of a blackish-grey colour, while the internal substance was traversed by black lines, or veins, in all directions. The specific gravity of these stones is mentioned, as varying from 3.6 to 3.7; and the specimen analyzed by Vauquelin, afforded to that eminent chemist,

Silica,	38.4
Alumine,	3.6
Lime,	4.2
Magnesia,	13.6
Iron,	25.8
Nickel,	6
Manganese,	0.6
Sulphur,	5
Chrome,	1.5
	98.7

The day on which these stones fell was remarkably calm and serene, the sun shone as bright as in one of the finest days of autumn, and not a cloud appeared above the horizon.

March 12, 1811. A meteorite of the weight of fifteen pounds, fell to the earth, in the village of Thonleghorosk, dependant on the town of Romea, in the government of Tschernigoff, in Russia. Its fall was preceded by three loud peals, like thunder. When dug from the depth of more than three feet, in a thick layer of ice, it was still hot. It was remarked, that, at the third detonation, there was an extraordinary explosion, accompanied with a loud hissing noise, and the diffusion of a great quantity of sparks. *Gilb. An.*

July 8, 1811. Stones, one of which weighed three ounces and a quarter, fell at Ballinguillas, in Spain. *Biblioth. Britan. T.* 48.

April 10, 1812. According to the report of D'Aubuisson, chief engineer of mines, about eight o'clock in the evening, a brilliant light was seen in the atmosphere at Toulouse, and for several leagues around. The people at first supposed that the powder magazine of Toulouse had been blown up; and when it was discovered that this was unfounded, the light and noise were ascribed to some extraordinary meteor; for the cold state of the atmosphere, and the force of the explosion, did not admit the idea of its being a simple peal of thunder. A few days afterwards, it was ascertained, that this phenomenon had been accompanied by a shower of stones, at two leagues W. N. W. of Grenade, in the communes of Burgave, Camville, and Verdun, situated in the departments of the Upper Garonne, and of the Tarn and Garonne. As some specimens were sent to the prefect of the Upper Garonne, that magistrate appointed a committee, composed of M. D'Aubuisson, M. Saget, of the Academy of Sciences, Marqué-Victor, professor of physics, and Carney, professor of mathematics, to proceed to the spot, and collect the details of the phenomenon.

The light which spread over the atmosphere burst forth all at once. Although the sun had set an hour and a half before, and the air was dark, the light was so brilliant, that the mayor of Grenade said he could read the smallest characters, and the mayor of Camville compared it to the light of the sun, adding, that the town-clock was as visible as at noon-day, and that a pin might have been picked up from the streets. The exact duration of this light was not remarked, some persons reckoning it at two minutes; others at one; and others at still less: but scarcely had it disappeared in the place where the meteorites fell, when there were heard in the air three violent detonations, similar to the report of large pieces of cannon, succeeding one another, with hardly any interval, and heard at Castres, twenty leagues from the spot where the stones fell. They were followed by a very loud noise, which some compared to that of heavy carriages rolling at once on the pavement; others compared it to the sound of several drums; and others to a strong fire of musquetry, from the Spaniards having invaded the country. This rolling noise seemed to issue from the N. E. and to proceed to the S. E.; and, after it had passed over the ground situated between the farms of la Bordette and La Pradère, a sharp hissing noise was heard, which ended in considerable shocks, similar to grape-shot striking the ground, and produced by the fall of the meteorites.

"I now," says M. D'Aubuisson, "give the information received, as to the Aërolites which were collected, or heard to fall.

"1. The inhabitants of the little farm called la Bordette, distinctly heard two aërolites fall; one to the northward, in a field adjoining, which they have not yet found: the other was found about fifty paces to the south-east: the fragment which we have weighs three ounces, and the whole stone did not weigh six.

"2. At the cottage called Paris, (300 metres above Pemejan) the inhabitants were at the door, listening to the rolling noise over their heads, when they heard the noise of a body which fell in front of them. The master of the house then went back through the house, to shut the door of a stable, and, when there, he heard a second large body fall. The interval between the two must have been about seventy-five seconds. This fact is of importance.

"3. At Pemejan, the inhabitants, equally alarmed at a stone which fell near them, took refuge in the house, when they heard a second hissing sound, followed by the noise of a body falling on the roof. Next day they found a tile broken, and a stone, weighing about three ounces, resting on the lath. Having carefully examined this spot, I found no contusion, nor any mark of fire on the wood of the roof. In the vicinity of the farm, two stones were found, which weighed only a few ounces.

"4. At Richard, after the rolling noise, an explosion was heard in the air, and next day a stone, weighing eight ounces, was found.

"5 At Pradère there fell, about one pace from the house, with considerable noise, and more than a minute after the detonations, an aerolite, weighing two pounds. It was not entirely sunk in the earth, and was not perceived until two days afterwards. A few seconds afterwards a smaller stone fell, forty paces in front of the house"

The quantity of meteorites that fell on this occasion probably much exceeded the small number collected; for the ground was partly in grass, and partly ploughed up; and the event took place when most of the inhabitants were in bed. The description of these stones so nearly accords with that of several others already specified, that it would be superfluous to note their aspect and properties.

April 15. 1812. A stone, of the size of a child's head, fell at Erxleben; and a specimen of it is in the possession of Professor Haussmann, of Brunswick. *Gilb. An.* T. 40. and 41.

August 5, 1812. Several stones, one of which weighed 65 lb., fell at Chantonnay, eight leagues north-west from Fontenay, in the department of La Vendée. Their structure is nearly analogous to that of the Barbotan specimens; but they contain such a large proportion of iron in the metallic state, that they are susceptible of a brilliant polish, and of bearing the graving tool.

March 14, 1813. A very remarkable phenomenon occured at the town of Gerace, in Calabria, and is described by Professor Sementini of Naples. The wind was westerly, and heavy clouds were approaching the land, over the sea. About two o'clock, P. M. the wind fell, and the sky became quite dark. The clouds then assumed a red and threatening appearance; thunder followed; and there fell red rain and snow, mingled with red dust. The alarmed inhabitants, conceiving that the end of the world was at hand, flocked to the churches. The red dust was very fine, became black when exposed to a red heat, and effervesced, when treated with acids. Its constituents were silica, carbonate of lime, alumine, iron, and chrome. What renders this precipitation the more remarkable is, that its ingredients are nearly the same with those of one of the varieties of meteorites; and hence they probably have a similar origin. According to Chladni and others, stones were observed to accompany the dust; and, if so, the intimate connection of the two appearances can no longer be reasonably questioned. Sementini's analysis of the red powder gave.

Silex, ...	33
Alumine, . . .	$15\frac{1}{2}$
Lime, ...	$11\frac{1}{2}$
Iron, ...	$14\frac{1}{2}$
Chrome, . . .	1
Carbon, . . .	9
	$84\frac{1}{2}$

Should the defect afterwards be found to consist of nickel and magnesia, we might then with safety maintain their identity.

On the present occasion, the coloured rain and snow seem to have fallen over a great extent of country; for red rain fell in the two Calabrias, and on the opposite side of Abruzzo, the wind being at east and south-east. Snow and hail, of a yellow-red colour, fell over all Tuscany, with a north wind. Red snow fell at Tolmezzo, and in the Carnian Alps, the wind being at north-east; and, finally, snow of a brownish-yellow fell at Bologna, the wind being south-west.

September 10, 1813. Samuel Maxwell, Esq. a gentleman of the highest respectability, and an ocular witness of the scene which he describes, communicates, in substance, the ensuing particulars to William Higgins, Esq. of the Dublin Society.

Friday morning being very calm and serene, and the sky being clear, about nine o'clock, a cloud appeared in the east, from which proceeded eleven distinct reports, somewhat resembling the discharge of heavy artillery. These were immediately followed by a considerable noise, not unlike the beating of a large drum, which was succeeded by an uproar, resembling the continuous discharge of musketry in line. The sky above the place whence the noise seemed to issue, became dark and agitated, emitting a hissing noise, and projected with great violence, different masses of matter, which shaped their course, with great velocity, in a horizontal direction towards the west. One of them, which was observed to descend, fell to the earth, and sunk into it more than a foot and a half, on the lands of Scagh, in the neighbourhood of Pobuck's Well, in the county of Limerick. Being immediately dug out, it felt hot, and had a sulphureous smell, with the whole of its surface uniformly smooth and black, the entire mass weighing 17 lb. Six or seven more, but smaller and fractured, alighted at the same time with great force, in different places, between the lands of Scagh and the village of Adare. Another very large mass passed with great rapidity, and a considerable noise, at no great distance from Mr. Maxwell, came to the ground on the lands of Brasky, and penetrated through a very hard and dry earth, to the depth of two feet. This last was not taken up for two days, when it was found to weigh about 65 lb. and to be fractured in many places. Another, weighing above 24 lb. and very heavy for its bulk, but exhibiting no symptoms of fracture, fell on the lands of Faha.

"There was no flash of lightning at the time of, or immediately before or after the explosion; the day continued very calm and serene; was rather close and sultry, and without wind or rain. It is about three miles in a direct line from the lands of Brasky, where the very large stone descended to the place where the small one fell in Adare, and all the others fell immediately; but they appeared to descend horizontally, and as if discharged from a bomb, and scattered in the air."

February 3, 1814. Stones fell in Bachmut, in Russia. *Gilb. An.* T. 50. Giese, who analysed a specimen, reports,

	90.50

September 5, 1814. In the 92d volume of the *Annales de Chimie*, M. de Saint-Amans relates the following circumstance of what he terms, not improperly, *uranolites*, near Agen.

A few minutes before mid-day, the wind being northerly, and the sky perfectly serene, a violent detonation was heard in the communes of Montpezat, Temple, Castelmoron, and Montelar, situated in the first, second, and fourth *arrondissemens* of the department of the Lot and Garonne. This unusual detonation was immediately followed by three or four others, at an interval of half a second, successively; and finally, by a rolling noise, at first resembling a discharge of musketry, afterwards the rumbling of carriages, and, lastly, that of a large building falling down. These strange noises, which proceeded from the centre of the department, were more or less audible within a circle of several leagues. The resemblance and volume of the stones which were precipitated to the ground, on the cessation of the explosions, appear to have been considerable. Some were sent to the prefect, who transmitted them to the minister of the interior, others were distributed among the curious, while many were picked up by the peasants, and venerated as reliques. Two are mentioned as weighing eighteen pounds each. It should seem that they were not found warm at the moment of their fall; that the heaviest sunk into a compact soil to the depth of eight or nine inches, and that one of them rebounded three or four feet from the ground. It is added, that they fell obliquely, making an angle of from 65 to 70 degrees with the horizontal line, and that they diverged in their fall, affecting various directions in the different communes in which they fell. "All the specimens of these stones which I saw," observes the reporter, "present no character to the eye which can make them be distinguished from those which I have hitherto had occasion to examine, or which I have in my cabinet: they merely seemed to be more friable and more porous than the latter." His account of the white cloud, too, which accompanied the meteor, corresponds with those of such as have more than once been observed to attend similar appearances.

July 3, 1814. A great shower of ashes in the river St. Lawrence. *Phil. Mag.*

November 5, 1814. "A singular phenomenon," says a native philosopher of the spot, "has occurred in the Doab. I have heard the facts related by various persons, who all concur in the same account. The circumstances are as follow: On the 5th of November, being Saturday, while half a watch of the day still remained, (*i. e.* half past four o'clock, P. M.) there was first of all heard a dreadful peal of thunder, and then stones rained down in sight of the inhabitants of the country, each stone being 13 or 15 seer* in weight. In the first place, wheresoever they fell a great dust rose from the ground; and, after the dust subsided, a heap of dust was formed, and in that dust were found the stones, a piece of one of which is sent herewith.

"In the district of Lapk seven stones were found; in the district of Bahweri, dependant on Bezum Sumroo, four; in the district of Chal, belonging to the pergunnah of Shawlif, five; at Kabout, belonging to the pergunnah of Shawlif, five. In all nineteen stones were found." *Phil. Mag. Biblioth. Britan.*

About the end of September, 1815, the south Sea was covered to a great extent with dust, supposed to have proceeded from the fall of a meteor. *Phil. Mag.*

October 3, 1815. At half-past eight o'clock, in the morning, the sky being clear and serene, with a gentle easterly wind, there was heard a rumbling noise like the discharge of musketry and artillery. This noise, which apparently proceeded from the north-east, and from a grey cloud of an indeterminate form, which hung over the horizon, had lasted a few minutes, when a man at work in a vineyard, at some distance from Chassigny, a village situated about four leagues to the south-east of Langres, and who had his eye fixed on the cloud, hearing a whistling like that of a cannon ball, saw an opaque body fall at a few paces from him, and which emitted a dense smoke. On running to the spot, he perceived a deep hole in the ground, with fragments of a peculiar sort of stone scattered around it. Having picked up one of the pieces, he found it as hot as if it had been long exposed to the ardent rays of the sun. In consequence of his having brought it into the village, several of the inhabitants went out and collected specimens. Next day Dr. Pistollet, physician at Langres, visited Chassigny, and having obtained one of the fragments, was struck with its resemblance to a meteorite which had been sent to him from Germany. He was, there-

* "The Bengal seer weighs 2 lb. and 2 drams."

fore, induced to repair to the spot, and collected about sixty small pieces, some of which were soft and wet, and easily crumbled in the hand; but all seemed to have belonged to one mass. In some of them the external crust was of a deep black, and in others of a glossy chesnut-brown. On the blackest crusts elevations or swellings were observed, like the produce of ebullition suddenly arrested. Internally, these specimens were grey-white, with a light greenish tint, granular, sufficiently soft to be scratched with a knife, composed of small brilliant and raised crystalline laminæ, and of a multitude of minute black ferruginous points, heavy, not magnetic, and interspersed with distant small round pores.

In this instance, Vauquelin's analysis afforded,

Silica	33.90
Oxidated iron	31
Magnesia	82
Chrome	2
	98.90

The Chassigny stones, therefore, are remarkable for their crystalline texture, for their want of nickel and sulphur, and for their more than ordinary proportions of magnesia and chrome.

April 15, 1816. Coloured snow again fell in Italy, particularly on Tonal and other mountains. It was of a brick red, and left an earthy powder very light and impalpable, unctuous to the touch, of an argillaceous odour, and sub-acid, saline, and astringent taste. Twenty-six grains, when analysed, gave the following results:

Silex	8
Iron	5
Alumine	3
Lime	1
Carbonic acid	.5
Sulphur	.25
Empyreumatic oil	2
Carbon	2
Water	2
Loss	2 25
	26

1806. A stone fell at Glastonbury, in Somersetshire. *Phil. Mag.*

May 2 and 3, 1817. There is reason to believe that masses of stone fell into the Baltic, because, after the great meteor of Gottenburgh, a stream of fire was observed from Odensee to descend rapidly into the sea, in the south-east. *Chladni.*

November 3, 1817. According to the French newspapers, a meteor of considerable size fell, in the morning, in the Rue de Richelieu, Paris, descending with so much force as to displace a part of the pavement, and to sink to some depth in the earth. It was accompanied by a sulphureous smell, and seemed to have been recently in a state of ignition or combustion. If such an incident really took place, it is to be hoped that some more distinct memorial of the particulars, and the exhibition of the stone itself, will not be withholden from the public.

In regard to the alleged fall of a great stone at Limoges, on February 15. 1818, and which Chladni probably copied from the public prints, the report seems to have been premature. See the new edition of *Nouveau Dictionnaire d'Histoire Naturelle*, t. 26, p. 270, in the margin.

July 29, O. S. 1818. A stone of seven pounds weight fell at the village of Slobodka, in the province of Smolensko, and penetrated nearly sixteen inches into the ground. It had a brown crust with metallic spots. *Edin. Journ. of Science*, No. 2.

Before closing our chronological register, it will be proper shortly to advert to the mention of various real or alleged meteoric masses, the dates of whose history can no longer be ascertained.

That which was preserved in the gymnasium of Abydos, as quoted by *Pliny*.

That which gave rise to the establishment of a colony at Potidæa. *Id.*

The black stone, and another deposited in the Caaba of Mecca.

The thunderbolt, described in Antar as black in appearance, like a hard rock, brilliant and sparkling, and of which the blacksmith forged the sword of Antar.

The mass of cellulsr iron, described by *Pallas*, *Chladni*, *Patrin*, &c. and found near Krasnojark, in Siberia. The tradition of the Tartars assigns to it an atmospheric origin; and the analogy of its aspect, texture, and chemical characters with those of other chemical bodies, whose descent from the air is no longer questioned, powerfully tends to confirm the tradition. Although the latter ascribes the formation of this extraordinary mass to a period which is lost in the remoteness of antiquity, its existence was first proclaimed, with the requsite circumstances of authenticity, to the learned of Europe in 1750, the year immediately subsequent to the discovery of a rich vein of iron ore, near Abakansk, by the Cossac Medvedief. As M. M. Mettich, inspector of mines, examined this vein, he remarked that it was about seventeen inches thick, and that it traversed a grey and compact hornstone, which apparently composed the whole mountain. About 150 toises to the west of this mine he discovered a mass of iron, which he conjectured might weigh unwards of thirty poods. Is was full of small, yellow, and rough stones, of the size of a kernel of the cedar cone; and it lay on the very ridge of the hill, which is covered with firs, without adhering to the rock. Being much puzzled to determine whether it had been formed naturally on the spot, or conveyed thither, he sought, with eager but fruitless diligence, for the slightest trace of any ancient iron forge. Dr. Pallas was likewise decidedly of opinion, that it could never have been produced in the rude furnaces or kilns of the Siberian miners, which were never known to yield more than fifty or sixty pounds of metal at a time; whereas the present mass, before any fragments were detached from it, weighed somewhat more than 1680 pounds. The iron is of a coarse spongy texture, little contaminated by impurities, perfectly flexible, and capable of being converted into small tools by a moderate heat. When exposed, however, to a high temperature, and especially when fused, it becomes dry and brittle, resolves into grains, and refuses to cohere or extend under the hammer. In its natural state, it is incrusted with a sort of varnish, which has protected it from rust; but when this coating is removed, or when broken in the state of bar iron, the usual process of oxidation very readily takes place. The cavities in the mass are filled with a transparent, amber-coloured substance, in the form of roundish grains or drops, presenting one or more flat and glossy surfaces. The mass has no regular form, but resembles a large, oblong, and somewhat flattened block, externally coated like the nodules of some of the blackish brown ores of iron. "This coating," says Pallas, "is also very rich in iron; and even the transparent fluor yields some pounds of iron in the hundred. Whoever will consider the mass itself, or large specimens of it, will not have the least doubt of its having been wrought by nature, since it has no one character of scoriaceous matters melted by artificial fire, or of those commonly found among volcanos. No volcanic ground, indeed, has been remarked nearer the mountains of Yenissei than the extinct craters of Daouria, situated at 1500 miles to the east.

The Siberian mass of native iron was first transported to Krasnojark, where it was found to weigh fifteen quintals. In 1772, it was conveyed to St. Petersburgh, and deposited in the collections of the Imperial Academy of Sciences. M. Patrin, who examined it in 1778, describes it as a large bomb, somewhat flattened, and partly covered with a rough ochraceous crust. So hard and compact was it in its natural state, that three or four forgers employed between ten and twelve hours in detaching from it a fragment of two pounds weight.

Of a similar description seems to have been the fragment which was found between Eibenstock and Johanngeorgenstadt.—Another, probably from Norway, preserved in the Imperial Cabinet of Vienna.—A small mass, of some pounds weight, kept at Gotha.—A mass, found under the pavement of Aken, near Magdeburg. *Loeber.*—A mass of iron from the coast of Honduras. *Annals of Phil.*—Scattered masses of black rock, containing native iron, on the right bank of the Senegal. *Compagnon*, *Forster*, *Golberry.*—A mass of iron at the Cape of Good Hope, in which Stromeyer detected the presence of cobalt. *Von Marum* and *Dankelman.*

In the *Philosophical Transactions* for 1816, there is an interesting history and account of a mass of native iron, found in the province of Bahia in Brazil, communicated by A. F. Mornay, Esq. to Dr. Wollaston. It is about seven feet long, four feet wide, and two feet in thickness, its solid contents being rudely estimated on the spot at twenty cubic feet, and its weight at 14,000 lb. The colour of the top and sides is chesnut, and the surface glossy, though not smooth, being slightly indented all over, as if hammered, while the hollow part underneath is covered with a flaky crust, whose external surface is rusty. Here we should not overlook, that the cavities, or indentations on the surface, are sometimes also observed on well ascertained meteorites. Thus one of the Siena stones is described by Mr. King, "as having many rounded cavities on its surface; as if the stone had been struck with small balls whilst it was forming, and before it was hardened, which left their impressions. And some appearances of the same kind," he adds, "were found on one of the four surfaces of another stone in the possession of Soldani." The surface of the Yorkshire stone, too, presents similar cavities or depressions. Wherever the Brazilian block is struck with a steel, it gives out abundance of sparks, and, when rubbed with a quartz pebble in the dark, it becomes beautifully luminous. It is not only magnetic, but manifests well-defined poles. Small fragments were detached from it with much difficulty, and revealed an internal crystallization, not previously noticed in meteoric iron. From the observations and experiments of Dr. Wollaston on the specimens transmitted to him, it appears that the texture of this iron is not only crystalline, but that it is disposed to break in the forms of the regular octohedron and tetrahedron, or in the rhomboid, a combination of both these forms.

"Though the fragments," observes the Dr. "are not in the least attractive as magnets, and have in themselves no polarity, they are precisely like any other pieces of the best soft iron, and assume polarity instantly, according to the position in which they are held with respect to the magnetic axis of the earth. When a long fragment is held in a vertical position, its lower extremity being then within 20° of the dip of the north magnetic pole, becomes north, and repels the north pole of a magnetic needle suspended horizontally. But this power is instantly reversed, by being suddenly inverted: so that the apparent contradiction between the observed polarity of the mass, and the seeming want of it in the fragments, is thus completely removed.

"Although Mr. Mornay reasonably expected, that this iron would not differ from the many others now on record that have been found in various parts of the world, and from his experiments was led to infer the presence of nickel, it appeared desirable to ascertain this point with more precision than he had been enabled to do, and to determine also in what proportion this peculiar ingredient of meteoric bodies might be found to prevail." Then, after detailing the steps of his process, he thus concludes:

"From the presence of nickel in this mass, we cannot but regard it as having the same meteoric origin with the various other specimens that have been found; and although in the spot whence it had been first removed Mr. Mornay discovered a bed of matter, from which it appears, by analysis, that similar iron might be formed by art, it seems by far more probable that an opposite change has really taken place, and that the whole of this supposed ore is the result of progressive oxidation during a series of years, of which we have no other evidence, and affords the sole ground on which a conjecture could be formed of the very remote period at which this problematic body has fallen upon the earth."

Since the expulsion of the Spaniards from the province of the great Chaco Gulamba, the country situated to the south of the river Vermejo, and to the west of the Parana, has been mostly abandoned. A few Indians only inhabit the district of St. Jago del Estero, to gather the honey and bees-wax which abound in the woods. These Indians discovered, in the middle of a very extended plain, a considerable mass of metal, which they reported to be iron. When the viceroy of Peru was apprized of this discovery, he was struck with the singularity of the phenomenon, because there are no hills in that part of the country, and scarcely a stone of any description is to be found within a circumference of a hundred leagues. Some individuals, regardless of every danger, and stimulated by the prospect of gain, repaired to the spot to obtain some portions of the metal, and actually conveyed specimens of it to Lima and Madrid; but the only fruit of their toils, was the assurance that the substance with which they had loaded themselves was very fine and malleable iron. According to these adventurers, the vein extended several leagues, and promised an abundant produce. The viceroy of Rio de la Plata, therefore, dispatched Don Celis to examine the mass with greater accuracy, and to fix some settlers in the neighbourhood, if he should judge the working beneficial. Celis departed, accordingly, from Rio Salado, on the 3d of February, 1783, accompanied by the requisite attendants; and, after performing a journey of seventy leagues, through a fine level country, he reached the spot, which, agreeably to his observations, is in 27° 28′ of south latitude. He found the ferruginous mass mostly buried in pure clay. Its external surface was very compact; but, on breaking some pieces from it, he perceived that its substance was full of cavities, as if the whole had at one time undergone fusion. In the course of separating 25 or 30 bits, the seventy chisels with which he had been furnished, were rendered useless. On removing the surrounding earth, he observed that all the surface which had been covered by the soil was invested with a layer of rust, of about six inches thick, and which he ascribed to the humidity of the ground. Having rent it in two different places by the force of gunpowder, he examined the deepest chasm, and found it precisely of the same nature with that of the surface, and also with the earth which was dug at a hundred paces to the east and west of the mass. As he could not conceive the latter, under the circumstances in which he found it, to be produced by any natural process, or conveyed by human means, he presumed that it must have been projected by some volcanic explosion. According to its cubical measure, and allowing a specific gravity somewhat greater than that of iron, this enormous mass should weigh about 300 quintals.

"The largest specimen of these substances which has ever been described," observes Mr. Southey, "has escaped the notice of all the philosophers who have written upon the subject.

"Walkennaer, in a note to Azara's Travels, upon the mass of iron and nickel found in the Chaco, says that two other such masses have been discovered; one which Pallas has described, and one which was dug up at Aken, near Magdeburg. Gaspar de Villagra, in his *Historia de la Nueva Mexico*, mentions a fourth, evidently of the same nature as these, and considerably larger than the largest of them. The tradition of the natives concerning it, supports the most probable theory of its origin. A demon, in the form of an old woman, appeared to two brothers, who were leading a horde or swarm of the ancient Mexicans, in search of a new country; she told them to separate, and threw down this block of iron, which she carried on her head, to be the boundary between them.

"Villagra describes it as something like the back of a tortoise in shape, and in weight about eight hundred quintals; he calls it massy iron; it was smooth, without the slightest rust, and there was neither mine near it, nor vein of metal, nor any kind of stone any way resembling it.

"The latitude where this is found is 27 N. The history of the expedition which Villagra accompanied, furnishes some clue for seeking the spot, and it might probably be discovered with little expense of time or labour, by a party travelling from Mexico to Monterry."

Humboldt's account of the Mexican sky-stone, reduces the above dimensions something more than a half; but still it remains greatly larger than any other that has been yet discovered. "In the environs of Durango," says this philosophic traveller, "is to be found insulated in the plain, the enormous mass of malleable iron and nickel, which is of the identical composition of the aerolithos which fell in 1751, at Hraschina, near Agram, in Hungary. Specimens were communicated to me by the learned director of the *Tribunal de Mineria de Mexico*, Don Fausto d'Elhuyar, which I deposited in different cabinets in Europe, and of which M. M. Vauquelin and Klaproth published an analysis. This mass of Durango is affirmed to weigh upwards of 1900 myriagrammes, which is 400 more than the aerolithos discovered at Otumpa by M. Rubin de Celis. M. Frederick Sonnenschmidt, a distinguished mineralogist, who travelled over more of Mexico than myself, discovered also, in 1792, in the interior of the town of Zacatecas, a mass of malleable iron of the weight of 97 myriagrammes, which, in its exterior and physical character, was found by him entirely analogous to the malleable iron described by the celebrated Pallas."

In the 42d and 44th vols. of Gilbert's Annals, mention is made of meteoric iron at Elbogen, in Bohemia, which originally weighed 190 lbs. A fragment detached from it, and fashioned into the shape of a coin, has the peculiar property, when put into weak nitric acid, of being attacked unequally, and of then exhibiting blackish particles, and others, of a whitish hue, in relief, whose mutual arrangements seem to depend on some law of crystallization. The Chevalier Schreibers, who first made this observation, found that it also applied to specimens of the Krasnojark mass; and he is inclined to believe, that it probably extends to all native iron that has fallen from the atmosphere.

Native iron is also supposed to have fallen near Lenarto in Hungary. *Gilb. Ann.* p. 49.

Two masses in Greenland, from which the Esquimaux manufacture a sort of small knives. Ross's *Account of an Expedition to the Arctic Regions. Edin. Journ. of Science*, No. I.

A few other detached masses of native iron have been quoted by different writers; but as they contain no nickel, and have a different texture from the preceding, their meteoric origin seems to be extremely doubtful.

From the foregoing historical review of our subject, we may safely deduce a few general observations, or corollaries.

That meteorites do really fall from the upper regions of the air to the earth, can no longer be doubted, unless we are determined to reject the evidence of human testimony. These bodies have a peculiar aspect, and peculiar characters, which belong to no native rocks or stones with which we are acquainted. Their fall is usually accompanied by a luminous meteor, which is seldom visible for more than a few minutes, and generally disappears with explosions. These bodies appear to have fallen from various points of the heavens, at all periods, in all seasons of the year, at all hours, both of the day and the night, also in all countries of the world, on mountains, and in plains, and without any particular relation to volcanos. The luminous meteor which precedes their fall, affects no constant or invariable direction. They are, for the most part, hot when they fall, and emit sulphureous vapours. As their descent usually takes place in calm, and often cloudless weather, their origin seems to be owing to some very different cause from that which produces rain or storms.

In our second volume, to which we beg leave to refer, we have unfolded our own sentiments relative to the very problematical source of these occasional visitants of our planet; and as these views still appear to us less exceptionable than any others which have been submitted to our notice, we shall glance at some of the latter with all suitable brevity.

The opinion of the Parisian Academicians, who, in the middle of the last century, maintained that the stones in question merely resulted from a stroke of lightning on the spot in which they were found, will not, in the present day, bear a moment's examination; for we have seen, that thunder and lightning do not necessarily accompany the fall of meteorites; and that these last differ from all the solid substances on the face of the globe. We will not deny, that lightning may tear up the soil, and convert it into a solid mass; but we have no proof of its competency to project masses, so formed, into an indefinite height in the atmosphere, nor to generate thousands of hard stones in fine cloudless weather.

The supposition that such concretions have been driven off from some of our volcanos, is scarcely less tenable; for the compound lavas of burning mountains are never found remote from the scene of their formation; and none of them present the aspect and characters of the bodies which we have described. Besides, most of the stony showers on record are represented as occurring when no remarkable volcanic eruption was known to have taken place. The ashes of a violent eruption have frequently, from their levity, been wafted to a considerable distance; but we are altogether unacquainted with any projectile force which can dart solid and heavy masses hundreds of leagues, through such a dense medium as the atmosphere. Mr. King, indeed, is inclined to believe, that an immense cloud of ashes, pyritical dust, and particles of iron, forcibly propelled from Vesuvius to a very great height, became condensed in its fall, took fire from its motion in the air, and its electrical elements, and thus gave birth to the Siena stones. But he does not thus account for the presence of nickel in their composition, nor for the other obvious discrepancies between volcanic ashes and meteoric stones. In order to explain the direction of the cloud which proceeded from the *north*, he has recourse to the supposition, that it was at first driven, in its course, to the northward of Siena, and afterwards urged back by a contrary current of wind. But the cloud itself, and its destinies, are alike gratuitous: and it is much more conformable to what we know of parallel cases, to conceive that the Siena phenomenon would have occurred at the time, and in the manner in which it did occur, although Vesuvius had remained in a state of perfect quiescence.

In the boldness of his speculations, M. Bory de Saint Vincent takes a still wider flight, and sends forth his meteorites from immense depths, in some early stage of the earth's existence, when ignivomous mountains, as he pompously denominates them, were endowed with propelling forces adequate to the dispersion of matter into the regions of space, in which they were constrained, for ages, to obey the compound laws of impulse and gravitation, until, in the progress of time, their spiral revolutions terminated on the surface of their native planet. Before, however, we can tamely acquiesce in the terms of such an extravagant hypothesis, we may be permitted to call for the evidence of the existence of those ancient and wonder-working volcanos, which could communicate planetary motion to chips of rock, without up-heaving the rocks themselves.

The sagacious Troili, too, in his endeavours to account for a fact which he has so triumphantly proved, labours to convince his readers that the Albereto stone must have been torn from the bowels of the earth, and projected to a great height by the powerful agency of subterraneous conflagration; and these conflagrations he conjures up at pleasure to suit his purpose. On such a supposition, however, the bursting of stones from the surface of the earth, and their ascent into the air, should be as frequently seen as their fall to the ground, and *some* of the profound openings and fissures occasioned by their violent passage through the strata, ought, before now, to have been observed; for we are not entitled to presume that they were *all* effected in the *recesses of forests*, or *closed again* after the stones had made their escape. Again, an expansive force commensurate to the conditions of the hypothesis, would occasion wide and ruinous disorder, which could scarcely fail to be observed in every inhabited country.

Of the many who contend for the atmospheric formation of meteorites, scarcely any two agree in regard to the manner in which such formation is effected. Muschenbroeck, in one part of his writings, ascribes the descent of stones from the air to earthquakes and volcanic eruptions; an opinion which later observations have disproved. In other passages, however, he leans to a modification of the atmospheric hypotheses, and attributes the origin of shooting stars to the accumulation of volatile matters suspended in the air. Whatever relation may subsist between shooting stars and fiery meteors, the former seem to move at a much greater distance from the earth than the latter, and occasion only a transient luminous appearance, in their passage through the upper regions of the atmosphere. The Dutch philosopher, however, adopts the common notion of their falling to the ground, and seems to confound their residue with *tremella nostoc*.

The late ingenious, but fanciful Patrin, who was solicitous to extend and illustrate his favourite doctrine of a regular circulation of gaseous fluids between the schistose strata of the globe and its surrounding atmosphere, very confidently deduced from this fancied circulation the occasional ignition and concretion of portions of these fluids in the higher regions of the air. But it is a sufficient confutation of his theory, that it rests on assumed and very improbable foundations.

In aid of the same cause, M. Salverte had recourse to a very liberal exhibition of hydrogen gas, kindled by electricity during thunder storms. But we have shown that thunder and meteors are distinct phenomena; and this gentleman's magazines of hydrogen remain to be proved.

His countryman, M. Izarn, has dragged his readers into a tedious and somewhat obscure exposition of his own sentiments, founded on the principles of chemical combination; but we are not certain that we perfectly comprehend his meaning; and, at any rate, his inferences depend on admissions of gaseous substances, arranged in spherical masses in the superior regions of the air, and occasionally detached from their insulating medium, and brought into one capable of combining with them; a disposition of things which may, or which may not exist, but of which we are entirely ignorant,

M. Seguin thinks it not improbable that the constituent principles of meteorites being transported by chemical or mechanical means into the upper portions of the atmosphere, where a vacuum, the cause of the noise of thunder, is produced, there remain suspended by solution or otherwise; but, although disseminated, being pressed by the external strata which fill the vacuum, they unite, conglomerate, and form a mass, the more considerable in proportion to the quantity of materials which it encounters in this place. Now, granting to this philosopher his conjectural premises, we have again to repeat, that the fall of meteorites is independent of thunder, and that the noise of the explosion, which so much resembles thunder as to have been often confounded with it, is posterior to the consolidation of the mass.

In the 75th volume of the *Annales de Chimie*, M. Marcel de Serres enters into the discussion of the origin of meteorites: but much of his paper is occupied with a very rapid and imperfect recapitulation of the instances of their occurrence, and incidental notices of showers of sand, &c. His decided bias, however, is to the generation of these bodies in the atmosphere, from the contact of all the matters carried up by the evaporation, and the formation of metallic particles during the ignition. Yet, his solution of the problem is, on the whole, far from *luminous;* nor is he altogether insensible to the difficulties with which it is encompassed. The total absence of oxygen in the Lissa stone, in particular, strikes him very forcibly. It is, besides, extremely difficult to conceive the machinery by which an immense field of gaseous, or highly attenuated matter in the air, can be instantaneously reduced into the compass and consistency of a solid compact mass, of very moderate dimensions, and suspended in the air, as if by enchantment, until it explodes, and is precipitated to the earth.

Dr. Reynolds' Outline of the Theory of Meteors does not very materially differ from some of those to which we have just alluded; for it proceeds on the supposition that minute portions of the earthy and metallic compounds of the surface of the globe, being exposed to the sun's influence, will be volatilized by the absorption of heat, and thereby assuming the state of elastic fluids, will ascend, until they arrive at media of their own density, where, congregating into immense and highly concentrated volumes, they will explode, and exhibit all the appearances of meteoric stones and showers. But the elevation of particles of stone and iron, however much attenuated, to the enormous height of a hundred miles above the earth's surface, is scarcely conceivable on any principle with which we are acquainted; and their combustion and explosion, in such a lofty and frigid medium, are alike unsusceptible of satisfactory explanation.

We know not that Dr. Murray is more successful, when he insinuates, in one passage, that these bodies spring from the thunder storm, and when he resorts, in another, to the solvent agency of hydrogen, and the changes produced on different substances by the influence of the electric fluid. That truly philosophic traveller and observer, Humboldt, who studied the present subject with much attention, is decidedly of opinion, that meteorites are foreign to the confines of our atmosphere.

The romantic notion, that they are the products of lunar volcanos, has derived some countenance from the speculations of the celebrated La Place, Poisson, Dr. Hutton, and others, who have demonstrated the abstract proposition, that a heavy body, projected with a velocity of about 6000 feet in a second, may be driven beyond the sphere of the moon's attraction into that of the earth. But the existence of any such volcanic force in the moon is purely hypothetical; nay, the existence of volcanos at all in our satellite, begins to be very seriously questioned. Overlooking these considerations, however, as well as the combustion of sub lunar substances without the contact of atmospherical air, the occasional arrival of fragments of such lava on the surface of the earth would, on a fair computation of chances, imply such a copious discharge of volcanic matters, that the moon, by this time, should consist of hardly any thing else. Further, if we may be allowed to reason from analogy, we should expect the volcanic productions of the moon to exhibit varieties of aspect and composition, and not a definite and precise number of the same ingredients. The resistance which a body falling from our satellite would experience in its transit through our atmosphere, combined with the two-fold motion of the earth, may sufficiently obviate the ordinary objection derived from the comparatively moderate impulse with which meteorites usually impinge on the earth's surface, but affords no solution of the more formidable difficulty, deduced from the want of coincidence, in point of time, between the descent of these stones and the moon's position, she being as often in their nadir as in their zenith.

Dr. Chladni, who, for years, has devoted much of his attention to the history of meteoric stones, long since intimated his belief, that they are cosmical bodies, or fragments of planetary matter. As earthy, metallic, and other particles, form the principal component parts of our planet, among which iron is the prevailing ingredient, other planetary bodies, he affirms, may consist of similar, or, perhaps, of the same component parts, though combined and modified in a very different manner. There may also be dense matters, accumulated in smaller masses, dispersed throughout infinite space, and which, being impelled either by some projecting power or attraction, continue to move until they approach the earth, or some other body, when, being overcome by gravitating force, they immediately fall down. By their exceeding great velocity, and the violent friction in the atmosphere, a strong electricity and heat must necessarily be excited, by which means they are reduced to a flaming and melted condition, and great quantities of vapour and different kinds of gases are thus disengaged, which distend the liquid mass, until, by a still further expansion of these elastic fluids, the whole at length explodes.

Our principal objection to this sort of reasoning is, that the leading idea of portions of cosmical matter being allowed to revolve in space, and to terminate their career on the surface of a planetary orb, is stated in terms too vague and gratuitous; but it assumes somewhat of reason and consistency, when propounded with the particular development of which we have conceived it to be susceptible.

Although we have now allotted to this curious subject as much space as our limits will permit, we are still far from having exhausted its details; and we shall, therefore, conclude by recommending to the perusal of our inquisitive readers, Stepling *de Pluvia Lapidea;* Troili's Essay, already cited; Izarn *Lithologie Atmosphérique;* Bigot de Morogues, *Mémoires Historiques et*

Physiques, sur les Chutes de Pierres, 2 T.; Chladni *on the Siberian mass of Iron*, and his *Catalogue of Meteors*; Gilbert's *Physical Annals*; *Opusculi Scelti*; Bjorn *de Indole et Origine Aërolithorum Disquisitio*; Biot *Rélation d'un Voyage fait dans le Department l'Orne, &c.* Böttiger's *Observations on the Accounts given by ancient Authors of Stones said to have fallen from the Clouds*; Fulda's *Memoirs on Fire-Balls*; Cavallo's *Elements of Natural Philosophy*, vol. 4th.; Klaproth *on Meteoric Stones*; King's *Remarks concerning Stones said to have fallen from the Clouds*; Soldani's *Account of the Tuscan Meteor*; and various recent and scientific communications, contained in the transactions of learned societies, and in periodical journals, foreign and domestic; to the most important of which we have occasionally referred in the course of the article. (H. N. A.)

METEOROLOGY.

Meteorology may be defined that department of physical science which treats of atmospherical phenomena. This definition is immediately suggested by the original import of the word, as derived from μετεωρα, *meteors*; and λογος, *a discourse*. The word *meteors*, indeed, has, in our language, been almost exclusively confined to those *luminous* bodies, which are seen occasionally in our atmosphere, and whose appearance and motion have not hitherto been reduced to any definite law. In Greek, however, the word μετεωρα, (from μετεωρος, *high* or *elevated*,) was indiscriminately applied to all bodies, whether luminous or opaque, that appeared in, or were deposited from the atmosphere; and the term meteorology is still used in the same, or even a more extended acceptation. It denotes the investigation, not only of those atmospherical phenomena that are of comparatively rare occurrence, and may be more properly denominated *meteors*, but of the various changes also, that are observed to take place in the state of the atmosphere itself. But for this extended application of the word, the subject would be comparatively uninteresting, and could with little propriety be dignified with the appellation of a science. Bodies that appear only at irregular intervals, at a considerable distance from the earth, and perhaps but for a few seconds at a time, though unquestionably deserving of being noticed and recorded, are not likely soon to be subjected to any thing like accurate investigation, or ever to be interesting, otherwise than as objects of curiosity or conjecture. The case, however, is very different with those atmospherical phenomena, which, from their frequency or vicinity to the earth, immediately affect the comfort and subsistence of its inhabitants. These must be at all times interesting, and in the progressive advancement of physical science they are becoming every day more so, in consequence of the invention of various instruments, by which their effects may be more accurately estimated; and their causes, it is to be hoped, in due time unfolded and explained. It is chiefly to these last, therefore, as constituting the great principles of meteorological science, that we propose directing the attention of our readers in the present article, and shall purposely avoid dwelling, at any great length, on the state of meteorology previous to the invention of those instruments, by which, in modern times, this department of science has been enriched, or on such phenomena as have not yet been made the subject of any thing like direct experiment.

From the nature of the facts that form the subject of meteorological research, it might be inferred that they must, in all ages of the world, have attracted the attention of mankind. The diversified appearances of the sky, the changes in the temperature of the air, and the other vicissitudes in the state of the weather, can hardly fail to strike even the most careless observer; nor does it require any great intellectual exertion to perceive that these changes have an immediate and powerful influence, not only on the feelings and comfort of sentient beings, but also on the vegetable productions of the earth. To men in a rude state of society, such phenomena would be peculiarly interesting. Necessarily led, from their employments and mode of living, to spend a great proportion of their time in the open air, they would have frequent opportunities of observing the various appearances that preceded any material change in the state of the atmosphere, while, from the want of those conveniences which are enjoyed only in a state of comparative civilization and refinement, their comfort, as well as their curiosity, would prompt them to recollect every circumstance that seemed to predict the approach of such changes. We find, accordingly, that from the earliest times these phenomena have excited a general interest in all countries, and in every stage of society; nor is there any other subject, perhaps, on which popular maxims have been so numerous or so universally prevalent.

The first attempt to collect and reduce to any thing like a systematic form, the various prognostications of the weather, is to be found, we believe, in the writings of Aristotle, and his disciple Theophrastus. Long before their time, indeed, the Egyptians and other eastern nations, had recorded many interesting facts regarding atmospherical phenomena; but they appear to have considered these only as a branch of astronomy or astrology. Aristotle, in his book *de Meteoris*, treats the subject as a separate science, and in addition to the observations of his predecessors, records also a variety of his own, bearing evident marks of all that accuracy and acumen for which he was so eminently distinguished. In as far as observation is concerned, few were better qualified than he was to conduct meteorological researches, and we have only to examine his remarks on *dew*, to perceive how nearly he approached on some subjects, to the discoveries of more enlightened times. Unacquainted, however, as he was, with both the chemical and mechanical constitution of the atmosphere, his speculations were often necessarily vague, fanciful, and inconclusive; and notwithstanding all his ingenuity and industry, meteorology, as a science, could hardly be said at that period to have had an existence.

The more profound speculations of Aristotle, were succeeded by the treatise of his pupil Theophrastus, in which he collected, and arranged under distinct heads, the commonly received opinions on the subject of meteorological phenomena. The work consisted of four general divisions, viz.—the prognostications of rain, of wind, of storms, and of fair weather; and it may be inferred from these titles, that if the treatise was less scientific than that of his master, it was calculated to be more popular. The darkness which at that time hung over every department of physical science, afforded little prospect, even to the philosophical inquirer, of his being able successfully to investigate the causes of phenomena, so irregular in their recurrence, and so various in their appearance; but every man would feel more or less interested, in making himself acquainted with rules or maxims, however empirical, which might enable him in any degree to predict the approach of such phenomena. We find, accordingly, that the writings of Theophrastus soon became the standard work on meteorology, to which succeeding writers on the subject made neither very numerous, nor very important additions. It constituted the groundwork of the *Διοσημεια*, or Prognosticks of Aratus, afterwards translated, together with the phenomena of the same author, into Latin verse by Cicero. A fragment of this juvenile essay of the Roman orator, is still to be found among his works, and affords us no very favourable specimen, either of the poetical talents of Cicero, or of the meteorological knowledge of the ancients.

It is unnecessary to waste the time of our readers, in attempting to trace the progress of this branch of philosopny, during the later period of the Roman history. In the writings of Virgil, and many other classical authors, we find frequent allusions to the subject; but while popular prognostications were no doubt multiplying, meteorology, as a science, made little or no advancement. A great many facts, indeed, are to be found in Pliny, and Lucretius has attempted to assign these to their respective causes; but besides that the facts themselves are of a vague and general nature, the absurdities and superstitions with which they are blended, render them a fitter subject for the study of the moralist, than the investigation of the natural philosopher.

During the ages that succeeded the final overthrow of the Roman empire, it is not to be supposed that the science of meteorology made any sensible progress. These were, proverbially, the ages of darkness, when not only were the lights of ancient literature and science extinguished, but the march of the human intellect seemed to be for a time retrograde. To the irruption of the barbarous nations from the north has been ascribed the ruin of all that was most valuable in the monuments of antiquity, while the period of their reign is almost universally regarded as a blot in the history of the human race, on which the historian dwells only in the language of lamentation or contempt. This is no doubt, to a certain extent, true; and the condition of Europe, for several centuries of the period in question, did certainly present a striking contrast to the brighter era of the Roman government, when conquest was uniformly accompanied with all the refinements of literature and philosophy. With the exception, however, of the first two or three centuries, while Europe was still in an unsettled state, we are not sure that what are commonly called the dark ages have been always fairly represented, or that they are in reality worthy of the unmeasured reprobation with which they are generally treated Were we more intimately acquainted with them, we should perhaps find that not a little of the darkness in which they are supposed to have been involved, has arisen from our ignorance of their true character, and that the origin of many of those sciences which constitute the glory of modern times, may be traced to the very men whom we have been taught to regard as little better than barbarians. But however this may be, we cannot agree with those who represent meteorological science as having suffered largely in the common ruin which the destruction of the Roman empire brought on the philosophy of the ancients. Meteorology, as a science, had, in fact, little to lose, and as to the popular prognostications of atmospherical phenomena, which constituted by far the largest and most interesting portion of the subject, even among the Romans, they were just as likely to have been discovered and preserved by the barbarian conquerors as by their more civilized predecessors. Few, if any of these prognostics were the result of philosophical investigation, or profound research. They were of that nature, that philosophy could give no rational explanation of them, but as matters of fact they were equally level to the capacity of the illiterate and the learned; and in proof of this, we need only observe, that many of the maxims which are to be met with in classical authors respecting the changes of the weather, are still found in this as well as other countries, and that too among a class of men, who cannot be supposed to have derived their information from the writings of Greece and Rome. A general view of these commonly received opinions will comprehend all that was valuable in the science, if it may be called so, previous to the general use of meteorological instruments, or, in other words, up to about the middle of the last century.

Our limits will not permit us to enter into a minute detail of the maxims alluded to above, nor are they of so much importance as to require a particular enumeration. It may be useful, however, to notice some of the most popular, and what have been generally considered the most certain prognostications of approaching changes in the state of the weather, as serving at once to illustrate the history of meteorology, and to show what are still the most important desiderata on this branch of physical science. It would be difficult, indeed, if not impossible, to make such a classification of these prognostics, as to include the various and often fanciful opinions, that have prevailed on this subject. The most commonly received, however, may be arranged under the two following classes: 1st, The appearance of the sky; and, 2d, Phenomena that take place at or near the surface of the earth. In illustrating these, we shall have an opportunity of noticing certain atmospherical phenomena which cannot well be omitted, but which could not with so much propriety be introduced in any other part of this article.

To the first class belong those luminous bodies that occasionally appear in the atmosphere, and which have been denominated *meteors*, or *falling stars*. These bodies appear to be of different magnitudes, and even of various forms, though this last circumstance may perhaps be the effect of optical deception. In general they seem to be globular, continuing visible only for a few seconds, and moving with great velocity. Their course is on some occasions in a straight line, and on others curvilineal, rendered more distinct by the tail or luminous train which they leave behind them; and before disappearing, they are sometimes separated into several smaller bodies, accompanied with an explosion resembling thunder, more or less loud according to their magnitude or distance. It was long supposed, and has now been proved by the most incontrovertible evidence, that these explosions are followed by a shower of solid bodies of a stony or metallic substance, some of which have even appeared luminous in their descent after the explosion, and have been taken up before they had time to cool: (See METEORITE.) This last phenomenon, indeed, is of comparatively rare occurrence. Thousands of small meteors, as various in magnitude and brilliancy as the fixed stars, have been seen in all seasons, and in almost every variety of weather, unaccompanied either with explosions, or the deposition of solid substances; nor is it certain that even the larger and more luminous meteors, such as that of 1783, described by Cavallo, or one in 1811, an account of which was given by Professor Pictet in the *Bibliothéque Britannique* for May 1811, are always followed by a fall of meteoric stones. On the other hand, these stones have sometimes been observed to fall after a loud detonation, when no meteor was visible, though this may perhaps be accounted for, from its having been obscured either by the superior light of the sun, or the intervention of clouds. But however this may be, the appearance of large meteors, and the fall of meteoric stones, or, as they have very improperly been called, *aeroliths*, are phenomena that appear to be closely connected, and this is almost all that is known upon the subject. We deem it quite unnecessary, therefore, to enter into a minute account of the attempts that have been made to classify these luminous bodies, according to their form, colour, or magnitude. Whether they are all of the same origin, but varying in appearance, in consequence either of their different distances, or of some peculiar state of the atmosphere, or whether they are essentially different in their nature, are questions to which, in the present state of meteorological science, no answer can be given. As prognostics of the weather, they have in general been supposed to predict wind, as appears from various passages in ancient authors; and it is also commonly believed, that the wind which follows will blow from the point of the compass towards which the meteor is observed to move. One at least of the various hypotheses which have been proposed to account for these phenomena is interesting, inasmuch as it appears to explain, in certain cases, the connection between the motion of the meteor and the direction of the wind.

The hypothesis to which we allude, is that which ascribes meteors to certain vapours arising from the earth, and becoming ignited in the higher regions of the atmosphere. The origin of this opinion may be traced to Aristotle; but from the discoveries in chemistry, of which that author was in a great measure ignorant, it has assumed, in the hands of the modern philosopher, a more definite form. Halley, and after him De Luc, has endeavoured, on this principle, to account for some at least of the circumstances attending the appearance of luminous meteors. The latter supposes that falling stars proceed from a phosphoric fluid, ascending from some spot of the surface of the earth, which becomes visible only when, by decomposition in the higher regions, it takes fire, and light is disengaged. If such a fluid can be supposed to rise in a continued column, without mixing with the atmosphere, or being dispersed by wind, there is no difficulty in conceiving how it may produce the appearance of a falling star. When the upper extremity of the column has reached such a height as to be in a great measure above the region of the clouds and moisture, it may, from the dryness of the air, take fire spontaneously, as phosphorus is known to do when exposed to the atmosphere in its ordinary state; and ignition having once commenced, it may be communicated backward to successive portions of the column, till it arrives at a portion of the atmosphere sufficiently moist to extinguish it, or at some point where the column itself has been broken and separated. In these circumstances, it is obvious that the appearance would be precisely that of a falling star; and Mr. Forster has ingeniously applied the hypothesis, to account for the apparent relation between such phenomena and succeeding gales of wind. It has been long known that different, and even opposite currents of wind, may exist at different heights in the atmosphere at the same time; and the author just referred to has found, from various experiments and observations, that when the wind near the surface of the earth changes, it frequently blows from the same point from which the current above had previously blown. He observes, therefore, that De Luc's hypothesis, though he is far from embracing it as satisfactory, will sufficiently account for the relation above stated, by supposing that the column of phosphoric fluid is bent, previous to ignition, in the direction of the upper current; so that, when ignition commences, the luminous body moves towards the point from which that current then proceeds, and from which the lower current is afterwards to blow. It is a prognostication of wind, then, only in so far as it indicates a change that has already commenced in the higher regions of the atmosphere, but which has not yet taken place near the surface of the earth.

The above hypothesis, fanciful as it may appear, and inadequate as it unquestionably is to account for all the phenomena of meteors, points to a plausible explanation of another luminous appearance, the cause of which has not yet been ascertained, and which, though differing in many respects from the bodies above described, bears a sufficiently close resemblance to them, to be classed under the general head of meteors. We allude to the well known light called *Ignis Fatuus*, *Jack with a lantern*, or *Will with the wisp*, so named from the superstitious notions which have been attached to its appearance. It is generally seen in dark nights, over boggy and marshy ground, sometimes at rest on the surface, but generally in motion at the height of five or six feet, skipping from place to place, and frequently changing both in magnitude and form. On some occasions it is observed to be suddenly extinguished, and afterwards to reappear at a distance from its former position. Those who have endeavoured to examine it more closely, or who have been accidentally led to approach it, generally remark that it moves away from them, and with a velocity proportional to that with which they advance, a circumstance which has had no small influence on the fears of the ignorant and superstitious. A particular account of the ignis fatuus, as seen on two different occasions, will be found in Cavallo's Elements of Natural Philosophy, Vol. III. p. 329.

To apply the above hypothesis to the explanation of this phenomenon, let us suppose that some such phosphoric fluid as that mentioned by De Luc, arising from the decomposition of animal or vegetable substances, passes into the atmosphere, and continues to float there without mixing with the atmosphere itself, or being dissipated by the wind. We can then conceive that this fluid, having become luminous by some sort of ignition, at the place where it is least affected by the intermixture of moisture or other substances, successively communicates with other portions of itself, so long as the column continues unbroken. In this way the luminous body will move from place to place, following the direction which the fluid had previously taken, and it will appear more or less brilliant, according to the quantity or purity in which the fluid exists at any given point. The occasional disappearance of the light may be owing to an interruption in the column, or to the quantity of phosphoric matter being so small as not to be visible till the ignition arrive at another point, where the inflammable matter is more abundant, and consequently reappears. We could anticipate many difficulties and objections to this explanation, which we doubt not will readily occur to our readers. But though we are not aware of any which might not admit of a plausible refutation, enough has been said on a subject that requires numerous and more accurate observations than any that have yet been made, to furnish the basis of a satisfactory theory.

Besides the meteors already described, there are other luminous appearances occasionally observed in the atmosphere, which belong also to the first class of prognostics, viz. *Halos*, *Parhelia*, or *Mock Suns*, *Paraselenia*, or *Mock Moons*, and the Rainbow. The investigation of these phenomena properly belongs to Optics, and to that article we refer for an account of such of them as have not already been described in the course of this work. (See HALO.) We notice them here, only because they are supposed to indicate certain approaching changes in the state of the weather. The luminous circle which is sometimes seen around the heavenly bodies, but especially the sun or moon, and which has received the name of Halo, or Corona, has, from a very early period, been regarded as a certain prognostication of stormy weather, accompanied with rain or snow, according to the climate or season of the year. It frequently happens, that, in the outer edge, or circumference of this circle, there is a part less distinctly defined than the rest, apparently owing to the contact of a denser cloud; and it has been remarked by shepherds and others, who have frequent opportunities of observing this phenomenon, that the storm generally comes from that point of the compass, towards which this indistinct portion of the circle, or opening as it is called, was directed. If there is any foundation for this remark, it may perhaps be accounted for on the principle already stated, regarding the change of wind in the higher and lower regions of the atmosphere. The current that is to bring the approaching storm may have set in above, before the halo disappears, and by accumulating the clouds upon it from that quarter, produce the indistinctness alluded to. This phenomenon, as well as its modifications the Parhelion and Paraselene, is obviously connected with a change of weather, only in so far as it indicates some peculiarity in the state of the atmosphere. The same remark applies to the rainbow, though this last is rather a concomitant, than a prognostication of rain. It has been remarked, however, that a rainbow in the morning is frequently followed by showers, while one in the evening forebodes fair weather.

It has been a long established, and generally received opinion, that the phases of the moon have a certain influence on the weather, and these have accordingly furnished various prognostications, which may also be referred to the first class. It is quite conceivable, on philosophical principles, that the atmosphere may be differently affected, in the same way as the waters of the ocean are, by the different positions of the sun and moon, relatively to the earth; and that the result in certain cases, may be a tract of settled or tempestuous weather, according to circumstances. At the same time the subject is still involved in great uncertainty; nor does there appear to be any foundation for the common opinion, that if the new or full moon happens about midnight, dry weather will follow; but if it takes place about noon, rain may be expected. The rule does no doubt hold in many instances; but on looking over our observations for a series of years, we find that it also frequently fails.

But the most fertile source of prognostics of the first class, is to be found in the various and ever changing appearance of the clouds. As the proximate cause of rain or snow, they have in all ages been regarded as affording the surest and most direct intimation of approaching changes; and there are few perhaps who are not conscious of having frequently looked, as it were instinctively, to the appearance of the clouds, in order to form some opinion or conjecture respecting the future state of the weather. At the same time, there are few subjects perhaps on which there exists so great a diversity and vagueness of opinion. Indications drawn from the appearance of the clouds themselves are exceedingly indistinct, unless when accompanied with other circumstances which render them more definite, such as the colour of the sky at sun-rise or sunset, the settling of clouds on the summit of hills, the appearance of mist or fogs at particular periods of the moon's age, &c. and though there are no doubt certain forms and modifications of clouds, which nine perhaps out of ten *weather-wise* persons would, without hesitation, pronounce indications of rain or snow; yet, if they were required to assign a specific reason for their opinion, scarcely two of them would be found exactly to agree. This uncertainty arises necessarily from the rapid changes which the clouds undergo, as well as the endless variety of forms which they assume, circumstances which seem to preclude the possibility of any thing like classification, or accurate description. An attempt, however, to supply this desideratum, was made a few years ago by Mr. Howard, a philosopher to whose ingenuity and researches the science of meteorology is not a little indebted; and though his system has been pronounced fanciful, which is perhaps to a certain extent true, it is even in its present state highly deserving the attention of meteorologists, and will in all probability sooner or later become the standard nomenclature of the clouds. As this part of our subject is designed to be strictly popular, we shall abstain at present from saying any thing on the origin and formation of clouds, and simply state the characters by which they are distinguished and described in the system referred to.

Mr. Howard defines a cloud, a visible aggregate of minute drops of water suspended in the atmosphere, and includes in this definition every such aggregate, whatever be its position relatively to the observer. Of course he comprehends under the term cloud, what are commonly called *mists* or *fogs*, because at a greater distance or elevation they are found to assume all the appearance, as they possess, according to his definition, all the qualities of clouds. He then proceeds to define the various forms and modifications of clouds, which he arranges under the seven following classes.

1. Cirrus.—A cloud resembling a lock of hair, or a feather. Parallel flexuous, or diverging fibres, unlimited in the direction of their increase.

2. Cumulus.—A cloud which increases from above in dense, convex, or conical heaps.

3. Stratus.—An extended, continuous, level sheet of cloud, increasing from beneath.

These three, Mr. Howard denominates simple and distinct modifications, constituting, as will immediately appear, the elements of every other variety. The two next are of what he calls an intermediate nature.

4. Cirro-cumulus.—A connected system of small roundish clouds, placed in close order, or contact.

5. Cirro-stratus.—A horizontal, or slightly inclined sheet, attenuated at its circumference, concave downward, or undulated. Groups or patches having these characters.

Lastly, says Mr. Howard, there are two modifications, which exhibit a compound structure, viz.

6. Cumulo-stratus.—A cloud in which the structure of the cumulus is mixed with that of the cirro-stratus, or cirro-cumulus. The cumulus flattened at top, and overhanging its base.

7. Nimbus.—A dense cloud, spreading out into a crown of cirrus, and passing beneath into a shower.

We have given these definitions in Mr. Howard's own language, but our limits will afford room only for a very condensed abridgment of his illustrations, and we refer our readers to the treatise itself, published in Tilloch's *Philosophical Magazine*, or Nicholson's *Journal*, vol. xxx. p. 35.

The Cirrus, he observes, is always the least dense, and generally the most elevated modification of clouds, sometimes covering the whole face of the sky with a thin transparent veil, and at other times forming itself into distinct groups of parallel threads, or flexuous fibres. Its height, according to Mr. Dalton, is from three to five miles above the earth's surface. It is generally found to be an indication of wind. When formed into horizontal sheets, with streamers pointing upwards, it indicates approaching rain; with depending ing fringe-like fibres, it is found to precede fair weather.

The cumulus is generally of dense structure, appearing after a clear morning, increasing from above, where its surface is convex, and forming, at its greatest magnitude, a pile of irregular hemispherical cloud. This takes place early in the afternoon, about the time of the greatest heat, and gradually diminishes towards evening, when it disappears. In this case it is an indication of fine weather.

The stratus is of moderate density, and comprehends those creeping mists which rise from valleys and lakes in calm evenings. It frequently disappears in the morning, and is then an indication of the finest weather.

The cirro-cumulus appears to be formed by the descent of the cirrus, the oblique denser tufts of the latter changing into the spheroidal form, when the cloud assumes the appearance of a ball of flax with one end left unwound or flying out. The cirro-cumulus sometimes consists of distinct beds, floating at different altitudes, the clouds appearing smaller and smaller, till they are lost in the blue expanse. It is most frequent in summer, and, when permanent, affords one of the surest indications of increasing temperature, and fine weather.

The cirro stratus assumes various appearances, from its being frequently connected with other modifications. By itself it is always an attenuated sheet, or patch, of an uniform hazy continuity when viewed over head, and of great apparent density towards the horizon. In this state it gives rise to the phenomena of halos, mock suns, &c. and indicates depression of temperature, wind, and rain. When it alternates with cirro-cumulus, the prognostic is doubtful. It is frequently seen resting on the summit of high hills, and in this state has been long regarded as foreboding rainy weather.

The cumulo-stratus is that fleecy cloud which is sometimes observed to settle on the summit of a cumulus, while the latter is increasing from beneath. It usually prevails in the completely overcast sky, and apparently without any regard to temperature, as it is found to precede either a fall of snow or a thunder-storm. Before the latter, it is frequently to be seen in different points of the horizon, rapidly swelling to a great magnitude. Its indication is doubtful, and must be determined by the prevalence of the other modifications that accompany it.

The nimbus generally appears in the form of a dense inverted cone of cloud, the upper part of which spreads in one continuous sheet of cirrus to a great distance from where the shower is falling. When the total evaporation of the cloud that remains after the shower takes place, it is reckoned a prognostic of fair weather. When the nimbus appears by itself, it generally moves with the wind, but when formed in the midst of cumuli, it sometimes moves in a contrary direction. This is often the case with thunder showers.

We do not think it necessary to pursue this subject any farther. The above sketch will be sufficient to enable such of our readers as are engaged in meteorological pursuits to record the appearance of the clouds, according to Mr. Howard's classification; and those who wish for farther information upon the subject may consult, besides the works already referred to, Forster's *Treatise on Atmospheric Phenomena*.

We come now to enumerate some of the prognostics of the second class, viz. those that are derived from phenomena, which are observed on the surface of the earth, or at least in the lower regions of the atmosphere. These phenomena are of various kinds, such as the expansion and contraction of flowers—the motions and cries of certain animals—painful sensations in the human body, &c. and though many of them are no doubt fanciful, yet others appear well entitled to the attention of meteorologists. Some of them indeed, especially such as are drawn from the economy of plants, admit of a philosophical and satisfactory explanation, as every body must know who is in any degree acquainted with phisiological botany. Thus it is stated, by Sir J. E. Smith, that "the *Convolvulus arvensis*, *Anagallis arvensis*, *Calendula pluvialis*, and many others, are well known to shut up their flowers against the approach of rain; whence the *Anagallis*, (or *Pimpernel*.) has been called the poor man's weather glass." It has also been ascertained, that the *Parliera hygrometra*, a Peruvian plant, uniformly contracts its leaves at the approach of rainy weather, which it predicts with the greatest certainty. See BOTANY. In these, and many other instances that might be given, the irritability of the plant is obviously excited by some change in the state of the atmosphere, which change is either the immediate cause, or concomitant of rain.

It is probably owing to some atmospherical influence of a similar kind on the animal system, that the peculiar cries or motions of some beasts, and certain sensations in the human body, are found to indicate changes in the weather, though it may be difficult, or in the present state of science, even impossible to explain that influence. Thus, it has been long observed, and very generally believed, that rain may be expected when swallows are observed frequently dipping their wings in the water over which they are flying—when the crow or the peacock cries louder and more frequently than usual—when water-fowl are particularly clamorous and active—when dogs appear unusually dull and sleepy—when the croaking of frogs is loud and general—or when worms are seen in great numbers on the surface of the earth. It is commonly supposed too, that the noise of sea gulls about the coast, and the approach of the porpus and dolphin to the shore, are certain indications of a storm at sea, and wind is generally expected at land when pigs are observed to run about with evident signs of uneasiness. It is equally well known, that persons subject to rheumatism and other similar diseases, or who have accidentally suffered injury in any of their limbs, generally feel more acute pain in the part affected before a change of weather, than at any other time; and we know instances in which these pains are most severe, before or during a sudden depression of the barometer. This coincidence points to something like an explanation of the phenomenon; but we avoid at present proposing any thing on the subject. Neither do we think it necessary to enter at greater length into a detail of facts with which our readers in general must be familiar, and of which they will find an extensive and amusing collection in Forster's treatise on Atmospheric phenomena, formerly referred to. We would only remark, in conclusion, that these popular prognostics, fanciful as many of them unquestionably are, and connected as they have too frequently been with the most absurd and ridiculous superstitions, ought nevertheless to find a place in every meteorological register; and to overlook them, is to reject the means which nature herself seems to have pointed out, for investigating her operations in a very interesting class of phenomena. We are aware, indeed, that the modern philosopher, who fancies that he can never depart far enough from the beaten track of vulgar opinions, may be disposed to smile at the idea of calling in the observations of the illiterate, to aid him in his scientific pursuits, or of attaching any importance to the pretended discoveries, as he may think them, of a class of men, who are always ready to trace cause and effect between any two events, however unconnected they may in reality be, provided they happen about the same time, or nearly at the same place. He ought to remember, however, that what has been stated as matter of fact by thousands in every age and country, as is the case with many of the prognostics alluded to above, is not to be rejected because it may appear to him fanciful or absurd—that instead of endeavouring to set it aside with a sneer, his own philosophy calls upon him to investigate the reality of the alleged phenomena in the first instance—and that, if it be as it is represented, he is bound by the principles of the same philosophy to admit it as a fact, whether he can assign the cause of it or not. He might be reminded too, of what is perhaps a very humiliating consideration, but not on that account the less true, that the shepherd, who is totally ignorant of the constitution and properties of the atmosphere, and altogether unacquainted with the laws which regulate the distribution of its heat and moisture, can, by his own experience and observation, predict the changes of the weather at a greater distance and with more certainty than the philosopher is able to do, with the aid of all the discoveries of modern science. This indeed, is not the only, nor as some may be disposed to think, the most interesting object of meteorological pursuits; but while it is in itself of generally acknowledged importance, it serves at the same time to demonstrate, that some at least of the popular maxims that prevail on the subject, are founded on fact, and are in reality the lessons which are taught in the school of nature herself.

It is far from our intention, by these remarks, to undervalue the researches of the experimental philosopher, or to insinuate that the study of meteorology should be confined to the collection and arrangement of such phenomena as have been stated above. On the contrary, we admit, that these phenomena, of themselves, can afford no accurate information, either as to the nature or extent of atmospherical changes. They may indicate these changes, but their indications are not susceptible of being correctly measured or definitely expressed. They are the result of certain influences exerted by the atmosphere in certain circumstances; but, like the expansions and contractions of the thermometer in its rude state, before the temperatures of melting snow and boiling water were ascertained to be fixed points, they are vague and indefinite quantities, and it remains therefore for science to supply this desideratum by the application of instruments, which, while they detect the operation of the same causes, may shew likewise the amount of that operation. Still, however, there is nothing unphilosophical in supposing that there may be many substances, both in the animal and vegetable kingdom, more readily affected by atmospherical changes, and consequently acting as meteorological instruments of greater delicacy than any that philosophy has yet devised, or art constructed; and it can never, therefore, be derogatory to the honour of science to avail itself of the aid of any class of phenomena, even though they may have been long and familiarly known to the vulgar and illiterate. Meteorology has already been indebted to some of the most common of these phenomena for the most valuable instruments that it now possesses; and there is nothing that forbids us to hope, that a more careful investigation of the above, and other similar facts, may not lead to the discovery of more delicate and important instruments than have yet been employed.

Though, in the preceding sketch, we have purposely confined ourselves to the popular view of meteorology, we are aware that this branch of our subject is far from being exhausted: but to have entered on a more lengthened detail, however interesting, would have exceeded the limits prescribed to the whole of this article. Our object, therefore, has simply been, to give our readers a specimen of what meteorology was in its early state, and of the progress which may be made in the investigation of the subject, independent of the instruments by which the researches of modern times have been assisted, and to which we apprehend the attention of philosophers has been too exclusively confined. We proceed now to consider the nature of these instruments, and the discoveries to which they have led.

Of Meteorological Instruments.

The atmosphere, as defined in another part of our work, is that invisible fluid which surrounds the earth on all sides, and which has been found, by various experiments, to be heavy, compressible, and elastic. For an account of the chemical and physical properties of this body, we refer to our articles Atmosphere, Chemistry, Pneumatics, &c. our business at present being only to explain the methods which have been employed to ascertain the nature and extent of the changes which it has been found to undergo. These changes chiefly refer to its *temperature*, *weight*, *moisture*, and *electricity;* and the instruments by which they are respectively measured, are the *thermometer*, *barometer*, *hygrometer*, and *electrometer*. The result of these changes is in some cases *wind*, and in others, *rain* or *snow*, which have also been subjected to measurement; the intensity of the former by the *anemometer*, and the quantity of the latter by the *pluvimeter*, or *rain-gage*. In describing the nature and application of these instruments, we shall endeavour to render our account intelligible to the general reader, from a conviction that a simple and popular view of their principles and use, is still a desideratum in works on meteorology. Many, we know, are prevented from taking an interest in the subject, from not understanding the nature or the application of the instruments to be employed; and if we can therefore in any degree contribute to the more extended use of these instruments, and consequently to the multiplication of meteorological observations, we shall consider our labours as of more service to the science in its present state, than the most ingenious theory, or the most profound speculations.

The *Thermometer* is an instrument employed for measuring the heat of bodies in general, and, among others, that of the atmosphere. It is a well-known fact, that all bodies are expanded, or have their bulk increased by heat, and are contracted or have their bulk diminished by cold, that is, when heat is abstracted from them. These variations of bulk are conceived to be proportional to the variations of heat, and it is upon this principle that the thermometer has been constructed. It consists of a glass tube AB (Plate CCCLXXIV. Fig. 1.) of a very small bore, having one extremity A blown into a bulb. This bulb and part of the tube or stem is filled with a liquid, generally mercury, which is found, on various accounts, to be of all others best fitted for the purpose. If the instrument in this state be applied to a body warmer than itself, the mercury will be seen to ascend in the tube; because the expansion of the glass being much less than that of the mercury, the bulb is no longer capable of containing the enlarged volume of the latter, which consequently rises into the empty part of the tube. In like manner, if the instrument be applied to a body colder than itself, the bulk of the mercury in the bulb being diminished, that portion of it which is in the tube will descend, to supply the diminution of volume; and this will be found to take place even when the tube is held in a horizontal position, the cohesion between the particles of mercury being such, as to admit of no separation of one portion of the mass from another. Hence it is obvious, that every change of temperature, that is, every increase or diminution of heat in the atmosphere, will produce, on a thermometer exposed to it, a corresponding expansion or contraction of the mercury; and it only remains, therefore, to find out some method of expressing the amount of these variations in such a way, as that the indications of one thermometer may be compared with those of another. This is accomplished by means of a graduated scale CD attached to the tube, the divisions of which are thus determined. It has been found that snow or ice in a melting state is always of the same temperature, and that the heat of boiling water, under the same pressure, is also uniform. These fixed points being determined, by immersing the instrument first in melting snow, and afterwards in boiling water, are transferred to the scale, and the distance between them is divided into a certain number of equal parts; the divisions being carried downwards below the melting, or, as it is improperly called, the freezing point, as far as is thought necessary, or as the scale will admit. Hence it is obvious, that two thermometers, having the freezing and boiling points thus determined, and the space between them divided into the same number of equal parts or degrees, must in similar circumstances uniformly indicate the same temperature. The divisions themselves will be larger or smaller, according to the relative capacities of the bulbs and stems, but this circumstance does not in any degree affect their indications. Neither is it necessary that the space between the freezing and boiling points should be divided into one number of parts rather than another. This is altogether arbitrary, and may consist of 50, 100, 1000, or any other that may be thought convenient. In comparing the indications of two thermometers, it is only requisite that the number in each be known, though it is certainly desirable that a uniform scale should be adopted.

According to the division generally used in this country, the space between the freezing and boiling points consists of 180 degrees. Fahrenheit, who first employed this scale, and whose name it still bears, imagined that the greatest cold that could be produced, is that which results from a mixture of snow and sea-salt, and he adopted that temperature as the commencement of the scale, which he accordingly marked zero, or *o*. He then exposed the instrument to the heat of boiling mercury, and having marked the point to which it rose, he divided the space between that point and the lower extremity into 600 equal parts. He afterwards found that the melting point of snow corresponded with the 32d division, and the boiling point of water with the 212th. Hence, in what are called Fahrenheit's thermometers, the freezing point is 32, and the boiling point 212, the difference between them being 180. The mode of graduating the scale originally adopted by Fahrenheit, has been long ago abandoned for that stated above; but the graduation itself, though liable to many objections, is still retained, and it is to this scale that all our references in this article are made. This graduation is represented on the side CD of the scale, in Fig. 1.

Among the various thermometrical scales that have at different times been proposed, that which is now generally used in France, and known by the name of the centigrade, is perhaps upon the whole the most eligible. The distance between the freezing and boiling points is divided into 100 equal parts, the freezing point being marked 0, and the boiling point 100. We must refer to our article THERMOMETER, for a particular account of the methods by which the indications of different thermometers may be compared; but we may here remark, that when any given temperature is expressed in degrees of the centigrade, it may be converted into those of Fahrenheit, by the following simple rule. Multiply the degrees of the centigrade by 9, divide the product by 5, and add 32 to the quotient. Thus when the centigrade stands at 25, Fahrenheit, in the same circumstances, will indicate 77, for 25 multiplied by 9, and divided by 5, gives 45, which added to 32 is 77. The divisions in every thermometer are numbered from zero downwards, in the same way as from zero upwards; but to distinguish them, the former are written with the negative sign or minus prefixed. Thus —15 means a temperature 15 degrees below 0. The degrees, according to this graduation, are represented on the side EF of the scale, in Fig. 1.

Thermometers are sometimes constructed of alcohol, or spirit of wine, which, though inferior in many respects to mercury, is on certain occasions preferable, and indeed necessary, as for example, in ascertaining temperatures below the point at which mercury freezes. In an alcohol thermometer, the freezing point may be ascertained by plunging it into melting snow, as stated above, but the other divisions must be determined by comparing it with a mercurial one, previously graduated as alcohol passes into a state of vapour long before it arrives at the heat of boiling water. Even mercurial thermometers are frequently graduated in this way, the tube in many of them being too short to admit of the instrument being exposed to so elevated a temperature.

In meteorological observations, it has been found very desirable to have some method of ascertaining the greatest degree of heat and cold, during any given interval, in the absence of the observer. Various contrivances have accordingly been employed for accomplishing this, by means of what are called self-registering thermometers. Those commonly in use are of a very simple construction. A mercurial thermometer, AB, (Plate CCCLXXIV. Fig. 2.) of a somewhat wider bore than ordinary, with a small bit of steel wire *a* over the mercury, so as to slide easily up and down in the tube, is placed in a horizontal position. As the temperature increases, the mercury pushes forward the bit of steel or index; but when the mercury again retires, in consequence of a diminution of temperature, the index remains behind at the highest point to which the mercury has risen. A thermometer AB (Fig. 3.) of a similar bore, but filled with spirit of wine, and having a small thread of glass *a*, about half an inch in length, immersed in the fluid, is also placed in a horizontal position. As the temperature diminishes, and the spirit sinks in the tube, it is found that the surface of the liquid does not pass the glass index, but carries it along with it, though, when an increase of temperature again takes place, and the spirit rises in the tube, the index is left behind at the lowest point to which the liquid had sunk. To prepare the instruments for a new observation, they are both inclined, so as to bring the index in each to the surface of the liquid, when they are again placed in a horizontal position. In referring to these instruments in the course of this article, we shall denominate the first a *maximum*, and the last a *minimum* thermometer. For a more particular account of the method of constructing these, and others of the same kind, see the article THERMOMETER.

In ascertaining the temperature of the atmosphere, by means of the thermometer, it is of great importance to attend to the situation of the instrument. It ought to be placed so as to be in the shade, not only at the time of observation, but during the whole day, and at such a distance from surrounding objects, as not to be affected by any changes in their temperature. We have repeatedly found that the reflection of the sun's rays from an opposite wall, though at the distance of 50 feet, and where there was a free circulation of air, has raised the thermometer several degrees higher than the actual temperature of the atmosphere. We have also found, that of two thermometers, graduated with the greatest care, and separated only by a thin bar of wood, the one on the upper side of the bar, from being more exposed to the sky than the other, has sometimes, during a clear night, stood several degrees lower. In meteorological observations, therefore, the thermometer should be screened from the sky, as well as from the reflection of the sun's rays. The bulb too should be exposed naked; and if it is accidentally wetted, it ought to be wiped dry before making an observation, otherwise it will indicate a lower temperature than it ought to do, from the influence of evaporation. In consequence of not attending to these sources of fallacy, we suspect that many of the meteorological tables that have been published, cannot be relied on as affording an accurate view of the temperature of the atmosphere.

The *Barometer*, we have already stated, is an instrument employed for measuring the changes that take place in the weight of the atmosphere. The principle upon which it is construeted may be explained by a very familiar example. If a tube, open at both ends, with a piston exactly fitted to it, have its lower extremity, to which the piston has been previously pushed down, immersed in water, on drawing up the piston, the water will follow it, and continue to do so till it rises to the height of about 33 feet. The same thing will take place if the tube be immersed in mercury, with this difference, that the mercury will ascend only to about the height of 30 inches. The effect in both cases is produced by the weight of the atmosphere. By drawing up the piston, the pressure of that weight is removed from the portion of the fluid immediately under it, while it continues to be exerted on the surface of all the rest. The liquid is therefore forced up into the tube, till the column be of such a height as to balance the weight of the atmosphere. If a glass tube of convenient length, and open at one end, be filled with mercury, and then inverted perpendicularly into a basin of mercury, so that the open end may be under the surface, the mercury will sink down from the upper extremity, and stand at the point to which it would have risen, had a piston been employed as stated above. In this form it constitutes a barometer, and the changes of weight which the atmosphere undergoes, are indicated by the rising and falling of the mercury in the tube. To measure these variations, a scale may be placed parallel with the tube, and divided into inches and decimals, beginning at the surface of the mercury in the basin. It is obvious, however, that if the scale be fixed when the mercury sinks in the tube, the surface of that in the basin must rise in proportion to the relative width of the basin and the tube, and consequently stand higher than the commencement of the scale; and in like manner, when the mercury rises in the tube, the surface of that in the basin must sink, and stand lower than the beginning of the scale. In the one case, therefore, the mercury in the tube will stand at a higher, and in the other at a lower point than it ought to do. This inaccuracy is in part removed, by making the basin very wide relatively to the tube, but still more effectually by constructing it in such a manner that the surface of the mercury in the basin may be raised or depressed to the commencement of the scale. In general a portion only of the scale is divided, viz. from the twenty-seventh to the thirty-first inch, reckoning from the surface of the mercury in the basin, because these are found to be the ordinary limits of the barometrical range. See Barometer.

It is hardly necessary to observe, that the barometer, in order to indicate correctly the weight of the atmosphere, should be placed in a perpendicular position. It should also have a thermometer attached to it, to be observed at the same time with the barometer itself, as the length of the column of mercury is affected not only by the pressure, but also, though in a much smaller degree, by the temperature of the atmosphere. Thus, if the barometer at the temperature of 32° stands at 30 inches, it would, under the same pressure at the temperature of 62°, stand at one tenth above 30 inches. The elevation of the place where the barometer is situated, is also necessary to be taken into the account. When carried upwards, the mercury is found to sink in the tube at the rate of about one-tenth of an inch for every 90 feet of ascent, (see Pneumatics) and consequently no comparison can be instituted, between observations of the barometer at different places, unless the heights of these places be accurately known.

Several plans have been proposed, and attempts made, to construct a self-registering barometer, for recording the greatest elevations and depressions of the mercury, in the absence of the observer. The contrivances are abundantly simple, but they are all liable to the same objection, that by increasing the friction, they diminish the delicacy of the instrument, thereby rendering it unfit for indicating minute changes in the pressure of the atmosphere. The simplest, and perhaps the best contrivance of this sort hitherto proposed, is described in our article Barometer. For representations of different forms of the barometer, see Plates LIII. and LIV.

An improved portable barometer, or rather a substitute for that instrument, has lately been invented by Mr. Adie of this place, which we shall shortly describe in the words of the inventor himself, as stated in the patent. The principle of the instrument, which Mr. Adie has denominated a *Sympiesometer*, consists in measuring the weight of the atmosphere by the compression of a gaseous column. It consists of a tube of glass ABCD, (Plate CCCLXXIV. Fig. 4.) of about 18 inches long, and 0.7 of an inch diameter inside, terminated above by a bulb D, and having the lower extremity bent upward, and expanding into an oval cistern A, open at top. The bulb D at the upper extremity being filled with hydrogen gas, and a part of the cistern A and tube BC with almond oil, coloured with anchusa root, the enclosed gas, by changing its bulk according to the pressure of the atmosphere on the oil in the cistern, produces a corresponding elevation or depression of the oil in the tube, thereby indicating the variations in the weight of the atmosphere. The scale for measuring these changes is determined by placing the instrument along with an accurate barometer and thermometer, in an apparatus where the air may be condensed or rarified, so as to make the barometer stand at 27, 28, 29, 30, or any other given number of inches. The different heights of the oil in the tube of the sympiesometer corresponding to these points being marked on its scale EF, and the spaces between being divided into an hundred parts, these divisions correspond with hundredths of an inch, on the scale of the mercurial barometer. To correct the error that would arise from the change produced in the gas by a change of temperature, the principal scale EF is made to slide upon another GH, so graduated, as to represent that change, and corresponding to the degrees of a common thermometer IK attached to the instrument. In this state, the rule for using the instrument is simply to observe the temperature by the thermometer, and to set the index *a* which is upon the sliding scale, opposite to the degree of temperature upon the fixed scale, then the height of the oil, as indicated on the sliding scale, will be the pressure of the air required. The sliding scale EF is moved by means of the knob L. We shall have occasion in another part of this article to notice the indications of the sympiesometer, as compared with those of the common barometer. See the *Edinburgh Philosophical Journal*, vol. i. p. 54.

The *Hygrometer* is an instrument of great importance in meteorology, as indicating changes in the humidity of the atmosphere. The idea of this instrument seems to have been first suggested by the expansions and contractions, which animal and vegetable substances are observed to undergo, when exposed to different degrees of moisture. We find accordingly that a great proportion of the hygrometers hitherto employed, have consisted of one or other of these substances, and though some of them are susceptible of great delicacy, they are all radically defective, inasmuch as the frequent changes to which they are exposed must in time produce a partial derangement in the texture of the substances, and consequently their indications become inaccurate. The only hygrometer that we think deserving the attention of meteorologists, is that delicate instrument the thermoscope of Count Rumford, or the differential thermometer of Mr. Leslie. This instrument has already been described, and its superiority to every other pointed out, in the article Hygrometry, to which we refer.* We apprehend, however, that it is not yet so perfect as to be incapable of farther improvement, and we have therefore to propose a modification of it, which we conceive is better adapted to the purposes of meteorology. In the course

* Our countryman, Dr. James Hutton, as we are informed by Mr. Playfair, was the first person who applied the power of evaporation to produce cold, to the construction of a Hygrometer, and was, therefore, the undoubted inventor of the *Thermometrical Hygrometer.* Mr. Leslie substituted, in place of the common thermometer, the *Thermoscope*, or differential Thermometer, invented by Count Rumford and himself. See Playfair's *Life of Hutton. Edin. Trans.* Vol. V. p. 67, note. Ed.

of our observations, we had long felt that a self-registering hygrometer was still a desideratum; and though it readily occurred to us that the differential thermometer might easily be constructed, so as to mark the greatest dryness in the absence of the observer, there appeared to be some difficulty in making it to register the greatest moisture. Both these objects are completely accomplished by the following simple contrivance, which, as far as we know, is the first attempt of the kind that has hitherto been made. We have already submitted it to the public through the medium of Blackwood's Magazine.(No. 12.) though we do not know that it has yet been adopted in any meteorological observations.

A tube, CD (Plate CCCLXXIV. Fig. 5.) such as is commonly used for constructing a self-registering thermometer, is bent upwards at C and D, and terminates in a bulb A. Into this bulb is introduced a portion of sulphuric acid, sufficient to fill the tube and a small part of the bulb; and along with the acid a small bit of glass *a*, of such a diameter as to move easily in the tube when the instrument is inverted. To the extremity D another bulb B is attached; and the air contained in both bulbs is so adjusted, that when they are at the same temperature the liquid stands at a point near the extremity D, and which is marked 0 on the attached scale EF. If the temperature of the bulb B be now increased, or, which produces the same effect, if that of A be diminished, the portion of air in the upper part of the bulb will contract, while that contained in B will expand in the same proportion, and the liquid will of course be forced from D towards C, the difference of temperature being indicated upon the scale in degrees, each of which, according to the graduation adopted by Mr. Leslie, is the thousandth part of the difference between the temperatures of freezing and boiling water. The divisions of this scale, which has been called the *millesimal*, may be thus determined: Let the bulb A be surrounded with melting snow, while the instrument is placed in an atmosphere of any higher temperature, say 50° of Fahrenheit, and let the point be marked at which the liquid becomes stationary. The distance between zero and this point, in the case supposed, will be 18° of Fahrenheit, or 100° of the millesimal scale, and that distance being divided into an hundred equal parts, will give the graduation required. The divisions may be extended beyond 100° if necessary, but in this climate a greater range will seldom be required.

To prepare the instrument for observation, it only remains to cover the bulb A with silk, and moisten it, taking care that the two bulbs be as nearly as possible of the same colour. The index, or small bit of glass *a*, is then to to be brought to the surface of the liquid, by depressing the extremity D, and the instrument to be exposed in a horizontal position. As the evaporation from the surface of the bulb A goes on, the air within contracts, from the depression of temperature produced by the evaporation; and the liquid is forced from D towards C by the elasticity of the air in B, carrying with it the index *a*. When the evaporation has reached its maximum, the liquid as well as the index becomes stationary; but should the process of evaporation diminish, the liquid will again move towards D, while the index is left behind, thus marking the *maximum of dryness in the absence of the observer.*

To find the greatest degree of moisture, another instrument is to be employed, which is represented in Plate CCCLXXIV. Fig. 6. The only difference between this and the former is, that the air in the two bulbs is to be so adjusted, that when they are at the same temperature the liquid may stand near the extremity C, the distance between C and zero being a little more than the length of the index *a*, and the bulb B is to be covered as A was in the former. The scale is graduated as before.

When the instrument is adjusted and exposed, evaporation goes on from the surface of B, and the liquid of course moves towards D; but when the evaporation diminishes, the liquid is again forced back towards C till it arrives at the index *a*, and should the evaporating energy, or dryness of the air, still continue to diminish, the index itself is then carried towards zero till the evaporation be at its minimum. The liquid then becomes stationary; and though it should afterwards mount higher, in consequence of an increased evaporation, still the index remains at the lowest point to which the liquid had sunk, thus marking *the minimum of dryness in the absence of the observer.* In both cases, as in the original form of the hygrometer, the covered bulb is to be kept continually moist with water, conveyed to it by filaments of floss silk from an adjoining vessel. We shall afterwards have occasion to notice the advantages of the above form of the hygrometer.

In our meteorological observations, we have been accustomed for several years to employ two delicate thermometers instead of a hygrometer, and find that they not only answer the same purpose, but have the additional advantage of showing the absolute as well as the relative temperatures of the two bulbs. The thermometers are of such a range as to admit reading off the tenth of a centigrade degree, which corresponds with a degree of Leslie's scale. The bulb of one of them is covered with silk kept constantly moist, and the difference of temperature between the two, expressed in tenths of a centigrade degree, gives the height of the hygrometer by the millesimal scale.

Of the *Electrometer* as a meteorological instrument, it is unnecessary to say much. It has never yet been regularly observed, except for a limited period, nor is it likely to be so soon. Our readers will find a full account of the various electrometers at present known under the article ELECTRICITY, with the results of observations made by some of the most delicate of these instruments. The difficulty of construction, as well as the want of a determinate scale by which to measure the intensity of atmospherical electricity, presents an obstacle to the general use of the electrometer, which we are afraid will not soon be surmounted, though the discovery of such an instrument on simple and accurate principles, could hardly fail greatly to extend the boundaries of meteorological science. That science indeed must always be in an imperfect state, so long as we have not the means of measuring the effects of the most active of all agents in the production of atmospherical phenomena.

The only other instruments connected with meteorology which we shall at present notice, are the *Anemometer*, *Rain-gage*, and *Atmometer*. The anemometer, or instrument for measuring the velocity of the wind, has already been treated of under that article, where its various forms have been fully described. Of these, Lind's is perhaps the most convenient, though Leslie's is unquestionably the most philosophical. The former measures the force of the wind by the height to which it raises a column of water in a bent tube, as indicated by an attached scale. A table shewing the velocity of the wind, corresponding to various heights in the column, is given at the end of the article Anemometer, from which it appears, that when the velocity does not exceed six miles an hour, the elevation of the water is so small as to render it impossible to ascertain the precise height of the column without the help of a vernier, a contrivance of which the nature of the instrument hardly admits. We have found, indeed, from experience, that it is quite impracticable with this instrument to determine the velocity of the wind with any thing like accuracy, unless it amounts to about 11 miles an hour, or what Lind calls a fresh breeze.

Leslie's anemometer is founded on the principle, that the cooling power of a stream of air is proportional to its velocity. It consists simply of a common spirit of wine thermometer having a pretty large bulb; and the force of the wind is deduced by an easy calculation, (see Anemometer,) from the time which it takes to cool through half the number of degrees which it had been previously raised by the heat of the hand. The result thus obtained, we have found in a great many instances to coincide almost exactly with that given by Lind, according to Hutton's calculations; the coincidence being always closest when the wind was so high as to admit of Lind's anemometer being accurately observed. It is to be regretted that the instrument has hitherto been so seldom used.

The *Pluvimeter*, or rain-gage, for ascertaining the depth of rain that falls on any given spot, is variously fitted up; but we shall confine ourselves to the description of one which we have used for many years, and which appears to us as simple, and at the same time as accurate, as any that we have yet seen. It consists of a copper funnel AB, (Plate CCCLXXIV. Fig. 7,) five inches in diameter at top, and inserted into a tube CD of the same metal, thirty inches in length, and one and a half in diameter, furnished with a stop cock E at the lower end. It is examined every morning at ten o'clock, and if any rain has fallen during the preceding 24 hours, it is measured by letting it off through the stop-cock into FG, a glass tube of .5 of an inch in diameter, with an attached scale of inches and tenths. By this means the rain that falls on a circular area of 5 inches in diameter is collected on an area of .5 of an inch, so that inches and tenths of water in the tube correspond to hundreths and thousandths of an inch of rain on the surface of the ground.

To prevent waste by evaporation, the communication between the funnel and the copper tube is made very narrow. The upper edge, or rim of the funnel, is also turned upwards from the inclined direction of the under part, so as to stand perpendicular, the better to prevent the rain that falls within the gage from being thrown over after striking against the interior. In some rain-gages, the rim is inclined a little from the perpendicular inwards. This we conceive to be wrong, as part of the rain that falls on the outside of the inclined rim may thus be thrown into the gage, which will consequently indicate a greater quantity than it ought to do. After all, however, the rain-gage is but an imperfect instrument. It gives only an approximation to the depth of rain in any case, and of small quantities it gives no indication at all, owing to the loss by evaporation before passing from the funnel into the tube. It is hardly necessary to remark, that the upper edge of the funnel ought to be parallel to the horizon, and that the instrument should be placed at a distance from any object that might screen it from the rain.

The *Atmometer*, or as it is sometimes called the *evaporometer*, for measuring the quantity of water evaporated in any given time, is an instrument which has not till lately been brought to any great degree of perfection. A circular basin of uniform width from top to bottom, filled with water, is the simplest form of the instrument; and the quantity evaporated may be very accurately ascertained by means of a graduated glass tube, similar to that described above for measuring the depth of rain. There are several difficulties, however, attending the use of the instrument, which render it a very uncertain indication of the absolute quantity evaporated. If it be exposed freely to the sun and wind, the heat acquired by the vessel itself will rapidly promote evaporation; and if the basin be kept nearly full, as it ought to be, the water will be agitated, and thrown over by the wind. Nor do we conceive, even though this last accident were guarded against, that the result would be either satisfactory or important. If the object of the atmometer be to ascertain the dissolving power of the air, it may be accomplished by placing the basin in a sheltered situation as well as if it were freely exposed, and if the quantity evaporated from the ground be required, the simplest and the most accurate method is that adopted by Dalton, as explained under the article Evaporation.

An atmometer, upon a very simple principle, was some years ago constructed by Mr. Leslie. It consists of a ball of porous earthenware two or three inches in diameter, into which is inserted a glass tube, so graduated that the quantity of water contained between two divisions of the tube, would cover the outer surface of the ball to the depth of one thousandth part of an inch. The ball and tube being filled with water, the top of the latter is covered with a brass cap, which by means of a screw and collar of leather is made quite air-tight, and the instrument is suspended out of doors, freely exposed to the wind. In this state the humidity exudes through the surface of the ball just as fast as it evaporates, and the descent of the column in the tube indicates the quantity evaporated. As the pressure of the atmosphere is, in a great measure, removed by the tightness of the collar, the water is prevented from passing through the ball so quickly as to drop, while the space which it leaves empty at the top is occupied by the very minute stream of air which is imbibed by the moisture on the outside, and may be seen rising through the water in the tube.

The instrument is very simple, but we have found, from numerous trials, that it is totally useless for a continued series of observations. The obvious impossibility of using it in frosty weather is itself an insuperable objection; but there is another which renders it equally unsatisfactory at all seasons of the year. Though a portion of air, as we have already remarked, is imbibed by the humid surface of the ball, and rises into the part of the tube from which the water has subsided, it is in so small a quantity as to exert very little pressure on the surface of the water. The consequence is, that during a shower, the rain that falls on the surface of the ball is forced into the interior, so that the water again rises in the tube; and though the elasticity of the air above must at length counteract this process, it is still sufficient to render the indications of the instrument altogether uncertain. As a proof of this, we shall mention one instance among several others that might be stated. On an evening of a dry summer day the water in the tube of the atmometer stood at 100°. During the night there was a heavy fall of rain, and next morning the surface of the liquid was as high as 15°. This fact, we apprehend, is decisive as to the merits of the instrument. Mr. Leslie has shewn, in his treatise on the relations of air to heat and moisture, that it may be successfully applied to various important purposes in the arts, and in certain circumstances to meteorological researches; but it is totally unfit for measuring the quantity of evaporation during an interval of any considerable length.

Since writing the above, we have received from the friend to whose hygrometrical researches we shall frequently have occasion to refer in the course of this article, a description of an Atmometer which he has lately invented, and which is undoubtedly the simplest as well as the most ingenious instrument of the kind hitherto proposed. It consists of a bent glass tube, ABCDEF, (Plate CCCLXXIV. Fig. 8.) of sufficient width to admit of a liquid moving easily from one part to another, and swelling out into the bulbs BC and EF. Into this tube at A is introduced a quantity of alcohol, which, after being conveyed into the bulb or wider tube EF, is thrown into a state of ebullition, and while the steam is issuing from A, the tube is there hermetically sealed, so that the air is completely expelled from the space ABCDE. The bulb BC is then covered with moistened silk or paper, and the instrument freely exposed. In consequence of the pressure of the air being removed from the surface of the alcohol in the bulb EF, a portion of that liquid passes into vapour, and occupies the empty part of the tube. Were the whole of the instrument at the same temperature, this process indeed would quickly be stopt by the pressure of the vapour itself on the surface of the alcohol; but as the bulb BC has its temperature reduced by the external evaporation from the moistened silk or paper, the vapour which rises from EF is there condensed, and runs down in a liquid state into the tube AB. This distillation goes on more or less rapidly, according to the degree of cold induced upon the bulb BC; that is, in proportion to the external evaporation; and, consequently, the quantity of liquid collected in the tube AB is a measure of that evaporation. When the atmosphere is completely saturated with moisture, or when the evaporation ceases, the temperature of AB will be the same as that of any other part of the tube, and the distillation therefore, for the reason already stated, will also cease.

The measure of evaporation thus found is expressed in inches, and decimals of an inch, by means of an attached scale GH, the divisions of which are determined by experiment. Suppose, for example, that the instrument is exposed in similar circumstances with an evaporating basin, and that the quantity evaporated from the latter in a given time, as determined either by weight or measurement, is found to be one-tenth of an inch, while the alcohol distilled by the former in the same time, fills the tube AB to the depth of one inch; then the scale being divided into inches and tenths, will indicate tenths and hundredths of an inch of evaporation. By increasing the proportion between the diameters of EF and AB, the quantity of evaporation may be measured to any degree of minuteness required. In using the instrument, the tube EF is to be sheltered from rain by enclosing it in a case or cover, to prevent its temperature being reduced below that of the atmosphere by subsequent evaporation, and the bulb BC is to be kept constantly moist by means of a small cup containing water attached to the tube immediately below it, the silk or paper being in contact with the water, or from an adjoining vessel, as in the case of the hygrometer. The instrument is placed in a vertical position, and is prepared for a new observation by inverting it, so that the distilled alcohol may be conveyed back to the tube EF. It is to be hoped that this beautiful and ingenious contrivance will soon meet with that reception among meteorologists, to which its merits so well entitle it. The instrument has already been constructed, and is found to possess the utmost delicacy. It is probable that it may, in time, supersede the use even of the hygrometer.

Application of Meteorological Instruments.

In considering the application of meteorological instruments, and the discoveries to which they have led, we shall follow the same order that we have observed in explaining their nature and principles. The first object of inquiry, indeed, and one which of all others has engaged the attention of philosophers, is the method of determining the average or mean temperature of the atmosphere at any given place. The solution of this problem is sufficiently interesting in itself, but it has become still more so from the other important questions which it involves. It is intimately connected with the determination of the law that regulates the distribution of heat over different climates, and it is only by accurately ascertaining the mean temperature of a place at different and distant periods, that we can ever hope to solve the question which has been so much agitated of late, whether the temperature of this country, or of the globe in general, is increasing, stationary, or diminishing. We shall, therefore, consider the subject at as great length as our limits will permit.

The most accurate method of ascertaining the mean temperature of any place, is to note the thermometer at the end of every indefinitely short interval, add all the temperatures together, and divide the amount by the number of observations. The quotient will give the average or mean temperature for the day, month, year, or any other period during which the observations were continued, and the shorter the intervals, the more accurate will be the result. This method, however, being for obvious reasons impracticable, various expedients have been proposed for approximating to the mean by a less laborious induction of facts. Indeed, the necessity of limiting the number of observations to two or three in the course of twenty-four hours, has been almost universally admitted; for however desirable it might be to have them taken more frequently, few are found to possess either leisure or patience for doing so. This remark must be understood as applying only to the thermometers that have hitherto been employed, for it is possible that a method may yet be discovered of finding the true mean temparature of any given interval, with the greatest precision. Such a method indeed has actually been proposed by Dr Brewster, by means of an instrument which he denominates an ATMOSPHERICAL CLOCK, and of which a short account will be found under that article. It was again noticed under the article BAROMETER, to which, as well as to the hygrometer, the principle is equally applicable. From the friction that must necessarily take place in such an instrument, the extremes might not perhaps be recorded with the same accuracy as by a delicate self-registering thermometer; but there seems to be no reason to doubt, that it would give the average of all the changes of temperature, pressure and moisture, with the greatest accuracy. As the Atmospherical Clock, however, has not yet been generally used, we must still inquire how the problem in question may be most accurately solved by the instruments described in the preceding part of this article. The only question therefore at present is, at what hours of the day and night ought the observations of the thermometer to be made, so as to give the nearest possible approximation to the mean temperature of the whole twenty-four hours.

For a considerable time after the thermometer came into general use, little attention seems to have been paid to the hours of observation, nor are they very rigidly adhered to, even by meteorologists of the present day. It is no uncommon thing to see in registers the state of the thermometer, morning and evening, without specifying at what hour of either the observation was made; or when the time is mentioned, to find it an hour earlier or later one day than another. Such registers may serve to gratify the curiosity of the individuals who keep them, but it is obvious they can add little to our stock of meteorological knowledge. Their results may accidentally approach to the mean temperatures of the places where they are respectively observed, but we have no certainty of their doing so, and in as far as they have hitherto been employed as data on which to found any theory whatever, they are worse than useless.

But the same objections are in part applicable, we suspect, to not a few even of those registers in which the observations have been uniformly made at certain hours of the day. In some we find the hours of observation six in the morning and noon, in others eight in the morning and two in the afternoon, in others nine in the morning and three in the afternoon, according to the convenience or particular opinions of the observers. In short, we seldom find two registers kept at the same hours, nor are the number of observations always the same. By some, one is considered as sufficient, provided it be made at the hour when, according to their theory, the temperature of the day is about its mean, while others observe two, three, or even four times, during the twenty-four hours. Now, without pretending to decide on the merits of the various hours of observation, or to determine which of them are most likely to give the nearest approximation to the true mean temperature, it must be obvious to every body, who is in the least degree acquainted with the fluctuations that are perpetually taking place in the temperature of the atmosphere, that such registers can admit of no comparison with one another. They may afford a tolerably accurate view of the relative characters of different years, at the respective places of observation; but unless it can be shown that their results approach all equally near to the true mean, they furnish no assistance that can be relied on, towards the solution of the important meteorological question, What is the difference between the mean temperatures of two places on the surface of the globe?

It might naturally have been expected, that after the invention of the self-registering thermometer, these differences in meteorological registers would have disappeared, and that whatever opinions individuals might entertain, as to the best hours for observing the actual state of the thermometer, they would at least record the maximum and minimum temperatures of every twenty-four hours. This, indeed, has in many cases been done, and has already contributed not a little to give a precision and accuracy to the subject which it did not before possess. Still, however, the use of these instruments has been more limited, and the results of their indications less attended to, than could have been wished. There seems to be a propensity too, among certain philosophers, to undervalue these results, arising perhaps from the difficulty which they find in reconciling them with certain preconceived notions and favourite theories of their own. It may be worth while therefore to inquire, upon what principle the mean of any two observations can be considered as a nearer approximation to the true mean of the twenty-four hours, than that of the maximum and minimum of the same period.

We cannot indeed pretend to demonstrate, that the mean temperature of any two or three given hours does not coincide with or approach very near to the true mean of the whole day and night; but it must be obvious, we think, that their agreement can be known only when the latter has been otherwise and accurately determined. Suppose, for example, that the mean temperature at any two hours, as eight in the morning and two in the afternoon, has been found by regular observations continued for a series of years to be 50°, what grounds have we to conclude that 50 is the true mean temperature of that place, unless it was previously known to be so, or without assuming as found, the very point which the observations themselves are intended to discover? It is not enough that we can assign plausible reasons of a theoretical nature, for supposing that it must be either exactly or nearly the true mean. The whole is a matter of experiment; and though we may have determined with the utmost precision what is the mean temperature of any given hour or hours, it still remains to be proved whether that agrees or disagrees with the true mean temperature of the day. We are disposed, therefore, to place very little faith in many of the opinions that are advanced, and the sweeping conclusions that are drawn, on this interesting subject. We have been lately told, for example, on the authority of Humboldt, that the mean, or half the sum of the maximum and minimum observed during the day and night, or through the summer and winter, does not represent the true mean temperature—and that between the parallels of 46° and 48°, the thermometer at sunset indicates nearly the medium temperature of the day. Now, in all this, it is obviously taken for granted, that the true mean temperature had been accurately ascertained by means independent both of the maximum and minimum, and of the temperature at sunset; and the question, therefore, still recurs, how was it determined?

As we have not had an opportunity of examining the original paper, in which this opinion is said to be advanced, we cannot give the solution of the question in Humboldt's own words; but if the abridgment of it given in Thomson's Annals can be depended on, it appears that the principle on which that opinion rests is merely a gratuitous assumption. The words of the abridger are these: "By comparing a great number of observations made between 46° and 48°, N. latitude, we find that at the hour of sunset the temperature is very nearly the mean *of that at sunrise and two hours after noon*." The amount, therefore, of Humboldt's discovery is simply this: That the temperature at sunset agrees more nearly with the mean of sunrise and two hours after noon, than it does with the mean of the maximum and minimum observed during the day and night; but it does not necessarily follow that it agrees with the true mean temperature of the day. It seems doubtful indeed whether Humboldt ever intended to draw any such conclusion. In the paper already alluded to, the reason assigned for making observations at sunrise and two hours after noon is, that the temperatures at these hours are considered as indicating the maximum and minimum. It is also stated, that if, besides the maximum and minimum, a middle observation be taken, it should be at least four or five hours from either of the others; but that, upon the whole, *the two observations of the extreme temperatures will give us more correct results.* It is to the daily extremes, therefore, that Humboldt ultimately appeals, as the standard by which to judge how near the temperature of any other hour approaches to the true mean, and if he has recommended any fixed period for making a single observation, it is rather with a view, we suspect, of abridging the labour, than of affording a more correct result. Such an abridgment is certainly desirable, but we are disposed to doubt whether it is at present attainable in the case of meteorological observations. The science is still in a condition that requires a copious induction of facts; and there is reason, therefore, to apprehend, that in proportion as we diminish the number of observations, we sacrifice accuracy to simplicity, and substitute theory for experiment.

Our readers will perceive, from these remarks, that we are inclined to consider the mean of the daily extremes, as approaching nearer than that of any other observations, to the true mean temperature of any given place; and the grounds of this opinion appear to us exceedingly simple and obvious. Were the actual temperature observed at very short intervals, say every half hour during the day and night, through the whole year, the mean of all the observations would undoubtedly give a very near approximation to the true annual mean; but it would obviously be still nearer, if, instead of these, the extremes of every hour were marked, and half their sum taken as the mean of the hour. The former method, indeed, would be equally accurate, did the temperature of the atmosphere suffer no interruption in its progress from one extreme to the other; but, liable as it is to frequent fluctuations, the most probable method of approximating to a correct estimate of these is, to note the extremes at short intervals. The same reasoning will apply, in some degree, to intervals of a greater length, though it may naturally be supposed, that, in proportion as these are extended, the result will be less accurate. We have found, however, from actual observation, that the difference between the means of the extreme temperatures, taken at shorter and longer intervals, is much less than at first sight we should have been led to expect, as will appear by the following results, deduced from our observations for 1817 and 1818.

	1817.	1818.
Mean of the 2 annual extremes . .	45.5	48.5
Mean of the 12 monthly extremes . .	45.4	47.5
Mean of the 36 extremes for each 10 days	45.4	47.4
Mean of the 365 daily extremes . .	46.1	47.2

These results, we think, furnish satisfactory evidence that the mean temperature derived from observing the daily extremes, cannot be far from coinciding with the true mean of the whole year; but even granting that it were otherwise, there are still arguments enough to demonstrate that these extremes ought to be recorded, in preference to any other observations. In determining the law which regulates the distribution of heat over the globe, we must be guided entirely by experiment. Calculations of the quantity of heat which is communicated to the earth in a given time, by the direct action of the sun's rays, or of the effects produced by the constant interchange of warmer and colder portions of the atmosphere, between one region and another, may be sufficiently amusing; but we shall look in vain to such calculations for the discovery of a law, which, as we have every reason to believe, is affected by so many disturbing causes, and modified by such a variety of circumstances. The combined effects of all these can be discovered only by collecting the results of observations in various situations, and under different latitudes. Nor is it enough that these observations have been carefully and regularly made. Before they can be employed as the foundation of any theory, it must be ascertained that they were made under similar circumstances. To compare the mean temperatures of two different places, which have been deduced from observations made at different hours, is to compare quantities that do not admit of comparison, and which, for any thing we know, may bear very different relations to the true means of these places. Now, the great advantage of recording, in all cases, the maximum and minimum of the day and night, would be, that every meteorological register would speak the same language, and put us in possession of the same physical fact. Even if they did not give us the true mean temperatures of the respective places where they are kept, (though, as we have already seen, their results would approximate to these quantities,) still the term mean temperature, which at present is used by every observer to denote the annual average of his observations, at whatever hours they may have been made, would have a definite and distinct meaning, expressing, in all cases, the middle point of the thermometrical range during certain periods. Till some such uniformity be established among meteorologists, the multiplication of registers will serve but little to extend the boundaries of this branch of science.

For the reasons now stated, we are not disposed to place so much confidence as many have done in the theorem given by Mayer, for determining the mean temperature of any given latitude at the level of the sea. We do not indeed quarrel with it because it is avowedly empirical, for it is only from experiment that any satisfactory rule on the subject can be deduced; but we entertain very considerable doubts as to the accuracy of the observations on which it is founded. We have already seen that, from the diversity of opinion that still exists respecting the best time for observing the temperature of the atmosphere, many of our meteorological registers are comparatively of little use; and we have no reason to suppose, that, previous to the middle of the last century, they were kept on a more accurate principle. The theorem, however, is valuable, as affording, by a very simple process, a general view of the diminution of temperature from the Equator towards the Pole; and though, in its present form imperfect, as we shall afterwards show, it may, by future corrections, become in time more accurate, as well as more extensively applicable.

The formula, as stated by Mr. Playfair in his Outlines of Natural Philosophy, is as follows. Let L be the latitude of the place whose temperature t is required, M the mean temperature of the parallel of 45°, and M+E the mean temperature of the Equator, then

$$t = M + E \cos. 2 L.$$

According to the observations collected by Mayer, M=58°, M+E=85°, and consequently E=27°. By substituting these numbers, the formula becomes

$$t = 58 + 27 \times \cos. 2 L.$$

When the latitude exceeds 45°, 2 L is greater than 90°, so that cos. 2 L becomes negative, or t is less than 58° The formula may be thus expressed at length. Multiply the cosine of twice the given latitude by 27, and add the product to 58; the sum will be the mean temperature of that latitude at the level of the sea. By this formula we have calculated the following table, showing the mean temperature for every parallel of latitude from the Equator to the Pole, expressed in degrees of Fahrenheit's thermometer. The table, strictly speaking, belongs to the subject of climate, which will be considered at greater length under the article Physical *Geography*; but as it is also intimately connected with the method of ascertaining the mean temperature, and as we shall have occasion hereafter to refer to it, in the course of this article, we have thought proper to introduce it here.

Lat.	Mean temp. at the level of the sea.	Lat.	Mean temp. at the level of the sea.	Lat.	Mean temp. at the level of the sea.

Mr. Leslie, in his *Elements of Geometry*, has expressed the above formula somewhat differently, and the results which he has deduced from it are also different. He assumes the mean temperature of the equator to be 29° centigrade, or 84°.2 Fahrenheit, and the mean of the pole comes out 32°. In all latitudes between the equator and the parallel of 45°, the mean temperatures in Mr. Leslie's Table are rather less than those in the above, and for higher latitudes somewhat greater. It appears, however, that the modification of the formula which he has employed, does not agree so well with the latest observations, as the original expression of Mayer, except in one case, where Mr. Leslie himself has applied it; nor do we find any satisfactory evidence in support of his opinion, that the law, as he has modified it, connects most harmoniously the various results of observations made at distant points on the surface of the globe. So far from this being the case generally, we can find nothing like harmony between the results of the Table and actual observations, even in that portion of the globe to which philosophers, previous to Mr. Leslie's extension of the law, considered the formula as applicable, viz. between the parallels of Stockholm and the Cape of Good Hope, and from the meridian of Stockholm westward to the coast of America. In proof of this, we shall extract from the meteorological observations collected by Humboldt for the purpose of determining the isothermal lines, or lines of equal temperature on the globe, the mean temperatures of a few places at the level of the sea, and compare them with the standard temperature as given by Mayer and Leslie, confining ourselves to such as were determined with the greatest precision, and from the greatest number of observations.

Place.	Latitude.	Temperat. accord. to Humboldt.	Temperat. according to Mayer.	Temperat. according to Leslie.
Ulea . .	65.° 3'	33.°0	40.°6	41.°3

Rome . .	41. 53	60. 4	60. 9	60. 9

The only instances in the above Table, where there is any thing like a coincidence between the result of observation and Mr. Leslie's formula, are those of Edinburgh and Rome, where the difference is exactly half a degree; but it would surely be a very unwarranted stretch in the adaptation of facts to theory, to set up two or three instances of agreement against so many and such glaring discrepances as the Table exhibits. The mean temperature of Edinburgh is said to be deduced from *six* years observations by Mr. Playfair. We suspect there is an error in this statement, as 47.8 is the mean of *three* years observations, viz. 1797, 1798, and 1799, as given by Mr. Playfair in the *Philosophical Transactions*. But however this may be, we are still disposed to regard the coincidence in this case, rather as accidental, than as affording any satisfactory evidence of the accuracy of the formula. The observations were made by Mr. Playfair three times a day, viz. at eight in the morning, one or two in the afternoon, and ten at night. Now, though it is impossible, from the well-known character of that eminent philosopher, to doubt the accuracy of Mr. Playfair's observations, still it is an assumption which is yet to be proved, that the mean temperature of these hours is the true mean temperature of the day; and even if this were proved, the error of half a degree is much too great to admit the application which has been made of the formula. According to our own observations, the mean temperature comes out considerably lower than that given by the rule, so that the difference seems in all cases to be on the same side, at least in latitudes above 41. At Kinfauns Castle, the seat of the Right Hon. Lord Gray, latitude 56° 24′, the mean of the daily extremes, for six years, from 1813 to 1818 inclusive, is 46°.3; and making allowance for the elevation of the place, (130 feet) 46°7. By Mayer's formula, it ought to be 47 7, and by Leslie's 48.1. The mean temperature of another place, under the same latitude, but more elevated and less sheltered, deduced from the daily extremes for five years, from 1814 to 1818, is 45°.7, and making allowance for the elevation 46°.2, which differs still more than the former from the result of the formula.

Another method, and perhaps the most correct of any, of determining the mean temperature of any given latitude, is by observing copious and well shaded springs. There can be little doubt that the mean temperature of the ground must, upon the whole, coincide very nearly with that of the atmosphere, from the well known tendency of heat to diffuse itself, so as to establish an equilibrium in temperature between two contiguous bodies. Every fluctuation of heat and cold at the surface will be communicated to the interior, more or less quickly according to circumstances, till the whole mass acquires the same temperature, while those fluctuations must obviously become less sensible in proportion to the depth below the surface. We are thus led to expect, that beyond a certain depth the temperature becomes stationary at or very near the mean temperature of the latitude; and the advantage of observing the temperature of a copious spring is, that at all times it will give an approximation to this quantity. At the same time, however, we cannot admit that this important element in meteorology can be determined even by the help of the most copious spring, with all the facility that has of late been supposed. A single observation at any season of the year has been represented as sufficient, not only to fix the true mean temperature, but, by a comparison with the standard temperature at the level of the sea, given by the formula stated above, to determine with precision the elevation of the place; an opinion which, besides leading to erroneous conclusions in particular cases, appears calculated to retard the general progress of meteorological science. Even the advocates for this summary method of determining mean temperatures, have produced only one instance of a spring in which there is scarcely any sensible increase or diminution of heat throughout the year, viz. the fountain of Vaucluse, whose temperature, it is said, does not vary *one tenth* of a degree, though, by some strange mistake, the variation is elsewhere stated, *on the same authority*, to be upwards of *two degrees*. This last quantity, we believe, will be found in general to be the range even of the steadiest springs, and no confidence therefore can be placed in any conclusion that may be drawn from a single observation. Before we can depend on such an observation, as determining the mean temperature, we must have previously ascertained, either that the spring does not sensibly change from one season to another, or that, at the time of observation, it was at its mean annual temperature. The remark applies still more forcibly to the measurement of altitudes. It is well known, and indeed may be inferred, from the very nature of springs, that the higher and more extensive the collecting surface of a spring, or the lower the point at which it issues, the more steady will be its temperature. In proportion, therefore, as the spring is elevated, the more liable will it be to variations, and the greater the necessity of multiplying observations to determine its mean temperature. Nor is this the only circumstance that affects the accuracy of the result thus obtained. The temperature of the atmosphere, in this climate, is found to diminish in proportion to the height above the level of the sea, at the rate of one degree of Fahrenheit for every 90 yards of ascent; so that an error of a single degree in taking the temperature of the spring, will produce a difference of 270 feet in the altitude of the place. Mr. Leslie has indeed given one instance, in which the elevation of two points on the same hill, determined in this way, agrees almost exactly with the altitude found by levelling; but it must be obvious, that a single coincidence of this kind, which might be purely accidental, is not sufficient to remove the objections now stated. The Crawley and Black springs, on the ridge of the Pentland Hills. were examined, and their temperature found to be 46°.2 and 45°. These quantities being subtracted from 48°.3, the standard temperature of the latitude at the level of the sea, according to Mr Leslie's formula, and the differences multiplied by 270, the products are 567 and 891, for the respective heights of the springs. The real heights found by levelling were 564 and 882. This coincidence is no doubt very remarkable; and there is one point in which it is perfectly satisfactory. The difference of temperature between the two springs is 1°.2, which, multiplied by 270, gives 324 feet for the elevation of the one above the other, being only 6 feet more than the real difference, as found by levelling. So far it illustrates the law by which a diminution of temperature takes place according to elevation; and had the temperature of the springs been compared with that of another equally permanent, at the level of the sea, we have no doubt that the absolute, as well as the relative altitudes, would have come out very near the truth. We have already seen, however, that the standard temperatures, as found by Mr. Leslie's formula, are far too vague and uncertain to be employed in a calculation, where a single degree above or below the truth produces an error of such magnitude in the result; and until these be verified by a more extensive induction of facts, the above coincidence must be regarded as purely accidental.

In April 1813, we instituted a series of observations on the temperature of water raised by an excellent pump, from the depth of 25 feet, and continued them till September 1816. The results of the whole show, that, even at this depth, the fluctuations of temperature are very considerable; but we shall confine ourselves to the observations of the two entire years, 1814 and 1815, that we may have an opportunity of comparing them with the means of the daily extremes in the open air. For a few months of 1814, the maximum and minimum were not observed, but the blank has been filled up from other observations, which have been found, for a series of years, to bear a certain relation to the mean of the extremes. The temperature of the water was taken three times a month, at equal intervals of 10 days; and the following table exhibits the mean of the three observations.

	Temp. of Water. 1814.	Mean of Extr. 1814	Temp. of Water. 1815.	Mean of Extr. 1815.
January,	44.3	25 1	43 4	31.9
February,	43.8	35.0	42 7	39.6
March,	42.2	37.0	42.5	40 1
April,	42.7	48.0	43 1	44 6
May,	44.1	48 0	44 5	52 4
June,	45.0	54 6	45.4	56 7
July,	45.7	61.1	46 1	58.4
August,	46 5	58 5	46.8	57.8
September,	47.2	53 7	47.4	53.4
October,	47.8	46.1	48.1	47.2
November,	47 5	39.1	48.4	36 1
December,	45.3	36.1	46.2	31 8
Mean,	45.2	45.2	45.4	45.8

It appears from the above table, that the temperature of the ground, at the depth of 25 feet, arrives at its minimum about the month of March, and at its maximum in October or November, according to circumstances afterwards to be noticed. The difference of the highest and lowest monthly average in 1814 is 5°.6, and in 1815, 5°.9; but if we compare the single observations of these months, we shall find that the range is considerably greater. In 1814 it amounted to 6°, and in 1815, to 6°.4. On the 20th of March, 1816, it stood at 40°.4, and on the 20th of August in the same year, at 48°.4, being a variation of 8°.

These facts are calculated to throw considerable light on the gradual diffusion of heat through the interior of the ground. From experiments lately made with thermometers placed at various depths, from one to eight feet, it is found that, during the summer season, a current of heat is passing regularly, but slowly from the surface downwards, as long as the mean temperature of the atmosphere is higher than that of the interior; and that in winter the current flows upwards towards the surface, to supply the deficiency produced by the external cold. In this way an equilibrium is gradually established in the temperature of the earth at moderate depths, and is found to take place twice a-year, viz. about May and October.

From all that we know of the nature and diffusion of heat, it is impossible to doubt the existence of such a current as is here stated; or its tendency in all cases to move from the warmer towards the colder region. In estimating its progress, however, a very important element seems in general to have been overlooked, we mean the influence of rain, in conveying heat or cold to the interior strata of the earth. The current alluded to might, perhaps, be thought sufficient to account for the fluctuations of temperature a few feet below the surface, but seems altogether inadequate to explain the changes which we have seen take place at the depth of 25 feet. A thermometer 8 feet deep does not arrive at its highest and lowest temperatures till two months after the extremes of the year; yet we find water at the depth of 25 feet reaching its extremes in less than three months. This fact, we think, can only be explained, by referring to the commonly received opinion respecting the origin of springs; which ascribes them to water deposited from the atmosphere on the higher grounds, and passing through the earth as a filter, till, being arrested by an impermeable stratum, it flows along the surface of that stratum, and bursts out in springs, or is intercepted by pits dug for the purpose. The rain and melted snow of winter, being cooled down on their first entering the ground far below the mean temperature of the interior of the globe, successively abstract, from the strata through which they pass, a portion of caloric; and though the quantity of water is not such as to cool the whole mass more than a few degrees below the mean temperature, yet it is obvious that the diminution must continue till the surface again approaches the temperature of the interior. This equilibrium will take place towards the middle or end of March, as the surface of the earth is then generally within a few degrees of the mean annual temperature. It is found, accordingly, that the temperature of the interior, as indicated by the pump water, is actually a minimum about the middle of March. From that period, it gradually increases, and appears to reach its mean about the middle of June. The rain and dews, however, of the succeeding months, being still at a comparatively high temperature, communicate additional heat to the strata beneath, and must continue to do so, till the surface of the ground again descend towards the temperature to which the interior has risen. This point, for the reasons already stated, will be a few degrees above the mean, and of course the equilibrium ought to take place about the beginning of October, as the temperature of the atmosphere is then generally within a few degrees of the mean annual temperature. It is obvious, however, that the ground, to the depth of several feet, may, from the accumulation of the sun's rays, be preserved at a higher temperature than the mean, even after that of the atmosphere has sunk considerably lower. This will happen to a certain extent perhaps every year; but especially in warm and dry seasons. Making an allowance, therefore, for this circumstance, the equilibrium between the surface and the interior, may be expected to take place about the end of October, which agrees exactly with observation, the pump-water being then a maximum. From this period the temperature decreases, and reaches its medium again towards the end of December.

But this view of the subject is still farther illustrated by several circumstances of a more particular nature. During the whole of the month of August, (1815.) when very little rain fell, the temperature of the water was stationary at 46°.8. In the course of September, and the first 15 days of October, when the quantity of rain considerably exceeded the evaporation, the temperature rose to 47°.8, being 1° in about fifty days; and between the 15th and 25th of October, during which time there fell upwards of two inches of rain, with little evaporation, it rose to 48°.8, being 1° in about one-fifth of the preceding interval. (See *Annals of Phil.* May, 1816.)

During the month of July 1816, though very wet, the temperature ranged only between 45° and 45°.7, the interior having then arrived at its mean annual temperature; but, in the course of 13 days in August, when a great deal of rain fell, the water rose from 46° to 48°.4. It is easy to see from these facts, that the interior of the earth may reach its extreme temperature sooner or later one year than another, according to the quantity of rain, and the periods at which it falls; and it is equally obvious, that every register of thermometers below the surface, ought be accompanied with a corresponding register of the rain gage.

But the most important fact established by the above observations, is the remarkable coincidence between the average temperature of the earth at the depth of 25 feet, and the mean of the daily extremes. Without resting on the result of 1814, when the observations of the maximum and minimum were for a time interrupted, that of 1815 is most satisfactory. Our observations on the pump water, did not extend to the conclusion of the year 1816, but taking the averages of the 12 months, from July 1815 to June 1816, during which time our register was carried on with the most scrupulous attention to accuracy, the coincidence is equally striking. The results are as follows:

Years.	Mean temp of water.	Mean temp of atmosph.	Difference.
January to December, inclusive, 1815. .	45.4	45.8	0.4 —
July 1815, to June 1816, inclusive, . . .	44.9	44.4	0.5 +

In the one case, the average of the water is four-tenths of a degree lower, and in the other it is five-tenths of a degree higher, than that of the atmosphere, which gives a mean difference of only *half a tenth* of a degree.

But it appears that the temperature of the ground at any depth, if taken regularly at equal intervals, will give a result, differing very little from the mean of the daily extremes in the open air. Since the beginning of 1818, we have observed the temperature of water issuing from a pipe, after passing through a distance of about 300 yards, at the average depth of 3 feet below the surface, and find that its mean annual temperature coincides very nearly with that of the daily maximum and minimum. The water, before being collected in the first or highest cistern, is brought in different directions, and from a considerable distance, in covered ditches, cut for the purpose of draining a large field. After issuing from the cistern, it is conveyed by an earthen pipe upwards of 200 yards before it flows from the stop cock, where the temperature is taken, and at every observation, which is made about the 5th, 15th, and 25th of each month, it is allowed to run five minutes, during which time the thermometer is found to become stationary. This mode of estimating the average heat of the interior appears to us to be more accurate, than sinking a thermometer to the same depth in any given spot, where the fluctuations of temperature must be more or less rapid and irregular, according to the nature of the soil. The following are the results of our observations.

Years.	Mean temp. of water	Mean temp. of atmosph	Difference.
January to December, inclusive, 1818, .	47.4	47.2	0.2
July 1818 to June 1819, inclusive, . . .	48.1	47.7	0.4

In both cases, the mean temperature of the water is higher than that of the open air, but the average difference is only *three-tenths* of a degree.

From these and the preceding facts, we think ourselves justified in maintaining, that the average of the daily extremes, found by a self-registering thermometer, may be more certainly depended on, as giving a near approximation to the true mean temperature, than observations made at any particular hours, and that in establishing this fact we are doing essential service to the science of meteorology. The great desideratum in thermometrical observations, is uniformity in the method of determining the mean temperature, and until such uniformity be introduced, this department of the science will still continue, what it has hitherto been, in a state of infancy. We admit, however, at the same time, that it is a very interesting inquiry, at what hour of the day the temperature approaches nearest to the true annual mean, and we shall now state the results of certain observations on this point, assuming the average of the daily extremes as the standard.

If the register kept by the Royal Society of London can be depended on, it would appear that the mean of 8 in the morning, and 2 in the afternoon, does not differ much from the mean of the maximum and minimum. Unfortunately, however, the observations are not always made at the same hours, nor has the self-registering thermometer, which was accidentally destroyed in November 1810, been since replaced. During the 16 years preceding that, viz. from 1794 to 1809 inclusive, the annual mean temperature at 8 in the morning, and 2 in the afternoon, was uniformly a little higher than the mean of the daily extremes, but the average difference for the whole period, amounted only to half a degree. Could confidence be placed in the accuracy of the observations, the result is a very important one; but strangely at variance with the opinion of a celebrated philosopher, stated in the Philosophical Transactions of Edinburgh, that the mean temperature at 8 in the morning, may be supposed to be nearly the true annual mean.

From our own observations we have found, that the average of 10 o'clock, morning and evening, coincides very nearly with that of the daily extremes. Owing to accidental circumstances, we cannot give a comparative statement of the two for the whole of every year, since the commencement of our meteorological register, but the following appear to be sufficient for establishing the fact. Taking the means as far as tenths, or one decimal place, the difference between the average of 10 morning and evening, and that of the daily maximum and minimum, is—

For 2 months of 1812, - -	0.0
11 months of 1813, - -	0.3
7 months of 1814, - -	0.7
12 months of 1815, - -	0.0
8 months of 1816, - -	0.3
12 months of 1817, - -	0.6
12 months of 1818, - -	0.3
7 months of 1819, (to this date,)	0.5
71	0.3

being little more than *three-tenths* of a degree, on an average of 71 months. In the general averages, the mean of the extremes, when there is any difference, is found to be always above the mean of 10 and 10; but it is not uniformly so, in the monthly average, excepting 1817 and 1819, when the excess was always on the same side. It might be inferred from this, that where self-registering thermometers are wanting, the mean temperature may be found with tolerable accuracy, by noting the thermometer daily at 10 morning and evening. According to the observations made at Kinfaun's Castle, the mean of the daily extremes, on an average of 6 years, is 1°.3 higher than the mean of 8 in the morning singly, and 1°.7 higher than the mean of 8 in the morning and 10 at night together.

In a paper inserted in the Transactions of the Royal Society of Edinburgh for 1800, Mr. Playfair proposed, instead of striking the average temperature once a month, as is usually done, to divide the whole year into decads, or portions of 10 days, and to find the mean of each. Twenty-one of these decads, viz. from the 20th of March to the 20th of October, he calls the vegetating season, and supposes that it is on the mean temperature of that season, that the quantity of the crop in a great measure depends. He assumes 40° as the lowest temperature at which corn will vegetate, and considers 56° as the mean temperature of a good vegetating season, so that the range between the mere germination of vegetables, and the fullest maturity to which they can attain in this climate, is 16 degrees. Mr Playfair gives the following as the result of his own observations for three years.

Years.	Mean temp. of the year.	Mean temp. of veget. seas.
1797	48.04	53.32
1798	49.28	56.17
1799	46.18	51.27

Whether the quantity of the crop, he adds, "may be expected to be proportional to the excess of the mean temperature of the vegetating season above 40, so that the crop of 1799 would be to the crop of 1798 as 2 to 3, or in a greater or less ratio. may deserve to be more accurately considered. There is reason however to think that the variations of the crop, at least corn, will be greater than in proportion to the variations of temperature; for if the mean heat of the vegetating season were to fall as much below that of 1799, as the mean of 1799 did below that of 1798, it would be reduced to 46, a temperature so low as would certainly prevent the ripening of corn altogether. By doubling the deficiency of the heat therefore, we do a great deal more than double the deficiency of the crop, so that the latter varies in a higher ratio than the former. The limit at which corn will not ripen, is probably higher than 46, and may perhaps be stated at 48."

In illustration of Mr. Playfair's theory, we shall state the mean temperatures of the seasons from 1815 to 1818. with the corresponding prices of meal, according to the fairs of the county where the observations were made. These prices cannot be supposed to be exactly in the inverse ratio of the quantities of grain, but still they will afford a general idea of the relative qualities of the crops.

Years.	Mean temp of the year.	Mean temp of veg. seas.	Excess above 40°	Price of meal per boll.		
1815	45.8	52.9	12.9	£0	14	0
1816	44.4	49.9	9.9	1	6	4
1817	46.1	50.5	10.5	1	6	0
1818	47.2	52 4	12.4	1	3	6

Many of our readers will probably recollect, that a considerable proportion of the corn crop in this country, in 1816, did not arrive at full maturity, and that its inferiority to that of the preceding year was much greater than the difference in the temperatures of the vegetating seasons. In both these respects, therefore, Mr. Playfair's conjectures are fully verified, and we have no doubt that a more extensive collection of observations on the principle which he has recommended, taking care to extend or shorten the length of the vegetating season according to the latitude, would throw much light on the interesting subject of climate; but we must leave this to be more fully discussed under the article PHYSICAL *Geography*.

As we have already found that observations of the thermometer at 10 morning and evening, give nearly the true mean temperature, there is reason to conclude that they are as likely as any other hours to give the mean height of the barometer and hygrometer, when these instruments are not constructed so as to register the extreme points to which they may rise or fall in the absence of the observer. Self-registering barometers are easily constructed, and have sometimes been used, but as from the increased friction they are not susceptible of great accuracy, we do not know that more satisfactory results are to be expected from employing them. It is difficult, indeed, to find two barometers of one kind, even by the best makers and on the most approved principles, that will exactly coincide, nor is it easy in any case, to avoid errors in adjusting the instrument for observation. From this circumstance, as well as from the irregularity formerly complained of in the times of observing, barometrical registers are perhaps still more imperfect than those of the thermometer. Before any comparison can be instituted between two such registers, it must be previously ascertained that the mercury employed in both barometers is of the same specific gravity, that the mode of adjustment, or contrivance for bringing the surface of the mercury in the basin to the commencement of the scale, is the same in each, and that the observations are made precisely at the same hours. These points being determined, it is still farther necessary to make allowance for difference of temperature and elevation, by both of which, especially the latter, the length of the mercurial column is considerably affected. Such of our readers as are conversant with the use of the barometer, must be aware of the difficulty of avoiding all these sources of fallacy, in registering the indications of that instrument. We have found from repeated experiments, which have been confirmed by those of an eminent artist. that in bringing the surface of the mercury in the basin to the point from which the scale commences, the adjustment should always be made in the same direction, and that it should not be elevated in one observation, and depressed in another. In our observations, whatever may be the state of the instrument, we uniformly bring the mercury below the true point, so that the final adjustment is always made by elevating the mercury in the cistern.

In order to exclude irregularities arising from difference of temperature, every barometrical observation might be reduced to what it would be, were the temperature of the mercurial column at 32°. This might be done very simply, and in most cases with sufficient accuracy, by allowing 3-thousandths of an inch for every degree that the temperature differs from 32°, and either subtracting that quantity from, or adding it to the observed height, according as the temperature is above or below 32°. The rule, strictly speaking, applies only when the observed height is 29.5, but in the ordinary range of the barometer, the error is not very considerable.

A similar correction might be made, and with great facility, for the difference of elevation between the positions of different barometers. It has already been remarked, that at moderate heights, the mercurial column sinks one-tenth of an inch for every 90 feet of perpendicular ascent. Every barometrical observation, therefore, may be reduced to what it would be at the level of the sea, by allowing 1-thousandth of an inch for every foot of elevation, and adding that quantity to the observed height. Like the former, this correction is only an approximation to the truth, but on a subject where there are so many other sources of fallacy, extreme accuracy in one point is, in the language of an eminent writer, an utter waste of the powers of calculation. We shall now illustrate the application of these corrections by an example.

Suppose the barometer is observed to stand at 29.565, the attached thermometer being at the same time 55°, or 23° above 32°, and the height of the place of observation 150 feet above the level of the sea, required the altitude of the mercurial column, corrected as above.

Observed height - - - - - -	29.565
Deduct for temperature, .003×23 - -	.069
Altitude if the mercury were at 32° -	29.496
Add for elevation of the place, .001×150	.150
Altitude at the level of the sea - -	29.646

Though these corrections are simple and of easy application, it is not likely that they will be generally adopted, nor, if they were, could we expect to find a very close coincidence between the results of different barometrical observations. The various degrees of delicacy in the instruments themselves, as well as of accuracy in observing them, are sufficient to prevent a constant harmony between two barometers, even when placed in the same circumstances; and we have often found that in the case of very slight fluctuations, one has been elevated, while another appeared to be depressed. At the same time, the observations that have already been made, have established some interesting facts regarding the simultaneous fluctuations in the weight of the atmosphere at different, and even very distant places.

In a paper drawn up by Professor Pictet of Geneva, and published in the second volume of Thomson's *Annals*, we have a comparative view of the state of the barometer at London, Paris, and Geneva, from 22d Sept. 1806 to 22d Sept. 1807. The elevations and depressions of the mercurial column are represented by curve lines, with the day of the month marked above or below the extreme fluctuations, so as to show at one glance both the time and the extent of these fluctuations. Were the changes in the weight of the atmosphere simultaneous and equal at the different places where the barometer was observed, and were the observations made at the same instant, and with the same degree of accuracy, it is obvious that the curve lines should be always parallel to one another. But though, in point of fact, this is found not to be the case, the deviations from parallelism are not greater than might be expected from the sources of difference and inaccuracy already noticed. The extreme elevations and depressions appear to take place generally on the same day, and nearly to the same extent; and it may be inferred, therefore, that changes in the weight of the atmosphere, at London and Geneva, are almost simultaneous. Pictet indeed has stated, that the fluctuation, when there is any difference in point of time, commonly takes place at London sooner than at Geneva; and he therefore lays it down as a general principle, that the disturbance of atmospherical equilibrium travels from the north towards the south. This principle, however, has not been verified by other and later observations. In a paper by Lord Gray, inserted in the 2d volume of the *Memoirs* of the Wernerian Society, a comparative view is given of the state of the barometer at Gordon Castle, latitude 57° 38′, Kinfauns Castle 56° 24′, Greenwich 51° 29′, and Plymouth 50° 26′ for 1814, and at the first, second, and fourth of the above places for 1815, on the same plan as that adopted by Professor Pictet. From this view, it appears that the fluctuations as before are nearly simultaneous; but when there is any difference in point of time, the change commences in the south just as frequently as in the north. We suspect, indeed, that this apparent difference is in a great measure owing to inaccuracy in observation. When the barometer continues either to rise or fall for a considerable time, its motion becomes slower as it approaches its extreme elevation or depression; so that between the evening of one day, and the morning of the next, it may have risen or fallen only a few thousandths of an inch. Unless, therefore, both observers are equally accurate, one barometer may have appeared to rise and the other to fall, and consequently the extreme elevation or depression to have taken place on different days.

The same uncertainty, arising from the same causes, attaches to many other observations that have been made, and conclusions that have been drawn, respecting the changes that take place in the pressure of the atmosphere. We allude particularly to certain periodical fluctuations, which, it is alleged, have been detected in the barometrical column, at different times of the day, and in different positions of the moon. We do not question the existence of certain causes operating on the atmosphere, and producing at regular intervals a change in its density; but we apprehend that amidst so many other disturbing causes, and where observations are so liable to error, we can know very little with certainty either of their nature or extent. Mr. Howard has stated, that on an average of ten years, he finds the barometer is depressed one-tenth of an inch, while the moon is passing from the quarters to the full and new; and elevated in the same proportion during the return to the quarter. There can be no doubt that the combined attraction of the sun and moon must operate more powerfully than that of either of them singly, in diminishing the gravity of the atmosphere; but whether the quantity of this disturbing force is such as can be estimated apart from others, is still we think very doubtful. A daily periodical fluctuation of the barometer has also been observed to take place within or near the tropics; but it does not appear to depend in any degree on the state of the moon. From a meteorological table kept at Seringapatam for 1816, and which we have now before us, we find that the barometer almost uniformly stands higher there in the forenoon than in the afternoon, at all seasons, and at every period of the moon's age. From the regularity of this change, there is no doubt that it depends on some fixed cause; but it seems very difficult to account for it, and the more so as the temperature is generally highest while the barometer is lowest. The multiplication of accurate registers in the tropical climates, where the range of the mercury does not exceed half an inch, may perhaps in time afford the means of solving this, as well as other interesting questions on the subject of atmospherical pressure.

In our climate, the fluctuations of the barometer seem to depend, in a great measure, on the direction and force of the wind. In serene and settled weather, the mercury generally stands about 30 inches at the level of the sea, and before or during storms it sinks below 29. The range is commonly stated at 3 inches, viz. from 28 to 31 inches; but it appears doubtful whether an accurate barometer on the sea shore will ever reach either of these extremes. According to the most accurate observations, the average height seems to be 29.830, and the range 2.5 inches. When the wind blows from the north-east or east, the mercury generally stands above the mean height, and below it when the wind is from the south-west. To this, however, as well as every other general maxim on the subject of the barometer, there are numerous exceptions. The greatest elevation of the mercury that we have observed during the last six years was on the 30th November, 1816, and it took place with a west wind. On the morning of that day, a barometer, 185 feet above the level of the sea, stood at 30.640, and in the evening at 30.602, corresponding respectively to 30.825, and 30.787 on the sea shore. Sudden or violent gales of wind are generally preceded or accompanied by a depression of the mercury, which continues to fall as long as the gale increases, after which it usually rises with as great rapidity as it fell. The greatest depression of the barometer that has been observed in this country for many years, took place on the 5th of March 1818, with a south-west wind. The weather, for a considerable time before, had been stormy and unsettled, with hurricanes of snow and rain from the west. On the evening of the 4th the wind shifted to the east, the barometer at the same time sinking rapidly. During the night the wind got round again to the south-west, and at eight on the morning of the 5th the barometer stood at 27.970, corresponding to 28.155 at the level of the sea. On the same night the tide rose unusually high in the river Tay, though it was only the first of the spring tides, being two days prior to the new moon; and at the time that these phenomena were observed in latitude 56° 24′, a violent hurricane was experienced at London, and various other places in the south of England. It frequently happens, indeed, that the barometer sinks during a gale of wind at a distance, while the atmosphere at the place of observation is calm and settled. We recollect having on one occasion, during close foggy weather, observed an unusual depression of the barometer, unaccompanied with wind, but afterwards found that it was contemporaneous with a violent and disastrous storm on the coast of Norway.

Many other facts might be stated, to show that the fluctuations of the barometer are almost always proportional to the strength and variableness of the wind. In the tropical climates, where the latter is gentle and steady, the range of the mercury is limited to a few tenths of an inch, but increases rapidly from the tropic towards the pole, where the winds are more violent and irregular. In like manner, the elevations and depressions of the mercury in the middle and higher latitudes, are greater and more frequent in winter than in summer. We have found, on an average of three years, that for the six months beginning with April and ending with September, the mean monthly range of the barometer, or the mean space between the highest and lowest observation during the month, is to that of the other six months in the proportion of 5 to 8. The same proportion will also be found to hold between the two seasons in the mean daily range. In our register for 1818, we noted in separate columns the differences between every two consecutive observations, which were made at ten morning and evening, and extended to a third column the sum of the two daily differences, as the range for the preceding 24 hours. The following is the result:

Mean range for 24 hours, from April to Sept. inclusive, - - - - - -	.174
Mean do. for the other six months, - -	.273

being nearly in the proportion of 5 to 8.

It appears from the reports of Captain Christian, who carried out one of Adie's sympiesometers to the East Indies in 1816; of Captain Ross and Lieutenant Robertson, who employed one on board the Isabella discovery ship; and of Mr. Stevenson, engineer to the Scots light house board, that this instrument is still more easily affected than the mercurial barometer by approaching gales of wind. From a register kept by Lord Gray of the contemporaneous indications of the sympiesometer and barometer, as well as from observations which we have had an opportunity of making with the same instrument, the former seems to be at least as delicate as the latter; but it is not quite apparent that the differences between the two instruments always indicate a greater degree of delicacy in the sympiesometer. We have now before us a register of that instrument for one month, with the corresponding indications of a very accurate barometer taken twice a-day, the range of the mercury during the period being from 29.190 to 30.380, and the temperature from 54° to 64°. Throughout the whole of these observations, the sympiesometer stood higher than the barometer, which might perhaps be accounted for from some inaccuracy in the construction of the instrument; but it is not so easy to explain the fact, that this difference has been gradually on the increase. At the commencement of our observations, it remained for some days nearly stationary at .030, but during the last eight days it has varied from .060 to .075. In the course of Lord Gray's observations a similar increase took place, which was afterwards however succeeded by a diminution. It would be premature, therefore, to decide on the merits of the instrument from such a limited number of observations, though they naturally lead to the suspicion that a certain degree of absorption has taken place between the oil and the gas. But however this may be, there can be no doubt that the sympiesometer is, on some occasions, affected by changes in the weight of the atmosphere, which are too minute to make any sensible alteration in the mercurial column, owing we conceive to the greater friction of the latter on the internal surface of the tube.

From these, and many other facts that might be produced, there can be no doubt of the relation between the fluctuations of the barometer and the state of the weather, particularly with regard to wind. It does not follow, however, that the latter can in strict propriety be assigned as the cause of the former. To say that such a relation exists, is merely the statement of two contemporaneous events, and still leaves the true cause altogether unexplained. Wind itself is the effect of some disturbance in the equilibrium of the atmosphere, by which the barometer must necessarily be affected, and it therefore remains to inquire by what means that disturbance is produced. We shall resume this subject, when we come to examine the phenomena of wind and rain; but before doing so, it will be necessary to consider the results of hygrometrical observations.

We have already had occasion to notice the imperfection of all the various hygrometers that were employed, previous to the invention of the thermoscope or differential thermometer; and we have still to lament that this delicate instrument has hitherto been so little used by meteorologists. It is also matter of regret, that in the few cases where it has been used, care has not always been taken to give either the precise time of the observation, or the corresponding temperature. The consequence is, that we know very little regarding the mean height of the instrument under any latitude, and still less of the true relative or absolute humidity of the atmosphere, even when its indications have been noted. To ascertain the true mean height, the self-registering hygrometer described above is perhaps indispensably necessary; but if the instrument in its simplest form has hitherto been so seldom employed, it is hardly to be expected that a more complex one will soon be brought into general use. In the mean time, however, there is a method by which this desideratum may, in part at least, be supplied. It has already been shewn, that the mean temperature at ten morning and evening does not differ from the mean temperature of the whole day, and since the relative humidity of the atmosphere depends not a little on temperature, it may be inferred that the mean of the hygrometer at these hours, will be an approximation to the mean of the day. It is upon this principle that we have hitherto registered the hygrometer, and we shall now state the mean height of the instrument, as well as of the thermometer, for each month of the last two years.

Months.	1817.		1818.

From the above, and other observations made in 1814, 1815, and 1816, it appears that the mean height of Leslie's hygrometer, situated 185 feet above the level of the sea, 20 miles from the coast, and under the latitude 56° 24′, is about 13 2. This fact, however, conveys no definite idea respecting the actual humidity of the atmosphere, nor can the indications of the instrument, taken by themselves, furnish us with any correct information on this subject. It has been shewn, under the article Hygrometry, that these indications are of no use, unless the state of the thermometer at the time of observation be also known, because it is found from actual experiment, that though the absolute quantity of moisture in the atmosphere should remain unchanged, the hygrometer will rise with an increase, and fall with a diminution of temperature. When the hygrometer stands at zero, or when the wet and dry thermometers indicate the same temperature, it may be inferred, whatever the temperature be, that the atmosphere is completely saturated with moisture; but should the temperature increase, the hygrometer will also rise, and continue to do so indefinitely, with every new accession of heat, though the actual quantity of moisture remains undiminished. In the article referred to, a formula is given, by which the indications of the hygrometer, which are of themselves vague and without any distinct meaning, may be converted into precise and definite expressions. The most important facts which may be deduced from that formula, are the three following.

1*st*, The point of deposition. It is known from the law which regulates the solution of water in the atmosphere, that a portion of air holding any given quantity of moisture in a state of vapour, will, if cooled down, arrive at a temperature where it will become saturated, or incapable of dissolving more moisture than it formerly contained, and consequently, if its temperature be farther diminished, it will begin to deposit a portion of that moisture in the form of dew or rain. The temperature at which it begins to do so is called the Point of Deposition.

2*d*, The actual quantity of moisture in a given portion of the atmosphere. This quantity is expressed by the formula in decimals of a grain in one cubic inch; but as the fraction is small, we have expressed it in our register, by decimals of a grain in 100 cubic inches.

3*d*, The relative humidity of the atmosphere. It was observed above, that in the hygrometer, zero is a fixed point denoting complete saturation, but that the scale extends upwards indefinitely, or in other words, there is no point in the scale which at all temperatures denotes absolute dryness. By the formula alluded to, this defect is completely remedied. Absolute moisture being denoted by 100, and absolute dryness by 0, it may be determined what intermediate degree of moisture is indicated by any given state of the hygrometer. This is in fact converting an indefinite into a definite scale, and by employing 100 to denote extreme moisture, all other quantities are expressed in hundredths of what would produce complete saturation. These three particulars may be illustrated by the following example.

Suppose that, at any given hour the hygrometer indicates 20, according to the millesimal scale, and the thermometer in the same circumstances 50; required the point of deposition, the actual quantity of moisture in 100 cubic inches of air, and the relative humidity.

By applying the formula, it will be found that the point of deposition is 40°.3 Fahrenheit, the actual quantity of moisture in 100 cubic inches of air 0.178 of a grain, and the relative humidity 73; that is, the atmosphere, in these circumstances, contains 73 hundredths of the whole moisture which it is capable of holding in solution at the temperature of 50, and which amounts to .178 of a grain in 100 cubic inches; and if the temperature were reduced to 40°.3, the hygrometer would sink at the same time to 0°, after which the moisture would begin to be deposited.

Let us suppose, now, that the hygrometer, as before, indicates 20, but that the temperature is 60. In this case the point of deposition will be found to be 53°.1, the actual quantity of moisture in 100 cubic inches 0 269, and the relative humidity 80. Such are the different degrees of moisture which may actually exist in the atmosphere, while the hygrometer stands at the same point.

We are aware that the labour and difficulty of calculating the result of each single observation may be urged, and indeed will probably operate, against the general use of the formula. This objection, however, it is to be hoped, will soon be in a great measure removed, by the labours of the same individual to whom the scientific world is indebted for the original and profound speculations of the article alluded to. Mr. Anderson proposes to construct a table, in which, from the indications of the hygrometer, in any given state of the thermometer and barometer, the three facts stated above may be found by inspection. In this table, we believe, the indications of the hygrometer are to be expressed in degrees of Fahrenheit instead of the millesimal scale, and the calculations are to be adapted to different heights of the barometer. In a table which we have constructed from the same formula, we have retained the millesimal division of the hygrometer, and adapted the whole calculation to one state of the barometer, viz. 29.640, which we found to be the mean height at the place of observation. The results are perhaps as near the truth as the nature of the subject requires; and at all events the errors arising from the fluctuations of the barometer cannot materially affect the annual mean. They are so inconsiderable, indeed, as scarcely to affect the accuracy even of a single observation, as is evident from the following example.

Suppose that on two different occasions the hygrometer indicated 30° and the thermometer 50°, but that the barometer in the one case stood at 30 inches, and in the other at 29. By the formula, the quantity of moisture in 100 cubic inches of the atmosphere expressed in decimals of a grain, is 146, when the barometer is at 30, and .144 when it is at 29, being a difference of only 002, corresponding to a fluctuation of one inch. A table, therefore, calculated for the mean height of the barometer, will be sufficiently accurate for all meteorological purposes.

It was inferred, from the principles investigated in the article HYGROMETRY, that the mean quantity of moisture in the atmosphere on any given day, will correspond nearly with what would produce complete saturation at the minimum temperature of that day; and this conclusion was verified by a reference to meteorological observations for 1815. From accidental circumstances, it cannot be expected that this coincidence should take place every day, but it was found to hold very nearly in the means of the whole year, and is farther confirmed by the following observations for 1818. The last three columns contain the mean results of 10 morning and evening.

Months.	Mean Minimum Temperature.	Mean Point of Deposition.	Grs. of Moist in 100 cub. inches.	Relative Humidity.
January,	32.1	32.0	.135	86.0
February,	30.8	29.9	.125	84.0
March,	31.8	29 5	.124	77.5
April,	34 0	28.9	.121	68 4
May,	43.9	43 9	.200	82.6
June,	50.2	48.9	.235	73 7
July,	52.1	53.0	268	81 0
August,	49.1	48.0	.228	76 2
September,	46.5	45.9	.213	80.0
October,	46 9	47.1	.222	87.1
November,	42.9	43.0	.194	88.2
December,	33.8	34 3	.145	86 3
Means,	41.2	40.4	.184	80.9

The difference between the point of deposition and the minimum temperature, in the above table, scarcely ever amounts to a degree, except in the months of March and April. In the latter it amounts to 5°; but this exception from the general rule may be easily accounted for, from particular circumstances. During that month the wind blew almost constantly from the north-east, so that a continual influx took place of dry cold air from the northern regions. This air, having its temperature increased by approaching a warmer climate, acquired also a greater capacity for dissolving moisture, and thus augmented the dryness of the atmosphere beyond what is natural to this climate; while, by the continuance of the wind from the same quarter, a new wave, as it were, flowed in before the preceding one could receive any sensible augmentation of humidity. A similar depression of the point of deposition below the minimum temperature, and arising from the same cause, took place in April 1817. During the present year (1819) the greatest depression, amounting to 3°.3, happened in the month of May, chiefly with east winds. In general the difference does not amount to a degree.

We have not thought it necessary to detail at length our observations with the hygrometer for the four years preceding 1818. In general the application of Mr. Anderson's formula to these observations, gives results corresponding nearly with those stated in the above table. It would appear, therefore, that at the place where the above experiments were made, the atmosphere, in its mean state, at 10 morning and evening, contains about 18 grains Troy in ten thousand cubic inches, being eighty hundredths, or four-fifths of what would produce complete saturation. A series of similar observations under other latitudes, and at different elevations, is still, however, a desideratum in meteorology; and till this be supplied, it would be premature to pronounce with confidence on any thing that has yet been advanced, respecting the law of aqueous solution in the atmosphere. At the same time, it is not too much, we think, to hope that Mr. Anderson's researches on this interesting branch of science will, when better known, lead to the discovery of some important facts on the formation of clouds, the production of rain, and other atmospherical phenomena.

The most satisfactory, and, at present, generally received theory, on the last mentioned subjects, (the formation of clouds and the production of rain) is that proposed by Dr. James Hutton, and first published in the *Philosophical Transactions of Edinburgh* in 1784. In this theory the author supposes, what has since been satisfactorily proved, that the dissolving power of air, or its capacity for holding water in a state of vapour, increases in a greater ratio than its temperature. From the experiments of Saussure, and others who have succeeded him in hygrometrical researches, it appears that while the temperature rises in arithmetical progression, the dissolving power of the air increases nearly in geometrical progression. This particular relation, however, is not necessary to the truth of the theory in question, which requires only that the humidity which the air is able to contain increase in a greater ratio than the temperature. This being admitted, it follows, that when two portions of air, of different temperatures, and both containing as much humidity as they are capable of dissolving at these temperatures, are mixed together, the joint quantities of moisture in the two portions will be greater than the air, after intermixture, is able to dissolve; and consequently a portion of the humidity must be condensed or precipitated. This will appear evident from the following geometrical representation.

Let the points A, B, C, D, (Plate CCCLXXIV. Fig. 9.) in the line AD, present different temperatures, and the perpendiculars Aa, Bb, Cc, Dd, the quantities of humidity which the air at these temperatures can hold in solution. From b and c draw the lines bef and cg parallel to AD, then Ce and Df will be each equal to Bb, and fg to ec; also ec and gd will represent the increased dissolving power of the air corresponding to the increased temperatures BC and CD But according to the theory, the former increases in a greater ratio than the latter; and consequently, if CD be equal to BC, gd will be greater than ec. Suppose, now, that equal portions of air, at the temperatures B and D, and both saturated with moisture, are mixed together; then the temperature of the mixture will be the mean between B and D, in this case C, and the portion at B, by having its temperature raised to C, will be able to dissolve ec more moisture than it did before, while the portion at D, by having its temperature reduced to C, will dissolve gd less than it did at its original temperature. But it was shewn that gd is greater than ec; therefore the quantity of moisture which the two portions of air held in solution in a separate state, is greater than what they are capable of dissolving after they are mixed, and consequently a portion of their humidity must be deposited by the mixture. This portion is obviously equal to the difference between ec and gd, or $=gd-ec$.

From the relation which the perpendiculars bear to one another, it is evident that the line passing through their extremities must be a curve, convex towards AD, and assuming what, from experiment, seems to be nearly the fact, that the dissolving power increases in a geometrical, while the temperature increases in an arithmetical progression, it will be a logarithmic curve. The knowledge of this fact enables us to assign, in certain cases, a precise value to the quantity deposited, or $gd-ec$. For, from the nature of the figure, we have

$$gd = \mathrm{D}d - \mathrm{C}c$$
$$ec = \mathrm{C}c - \mathrm{B}b$$

and subtracting these equations, $gd - ec = \mathrm{D}d - 2\,\mathrm{C}c + \mathrm{B}b = \mathrm{D}d + \mathrm{B}b - 2\,\mathrm{C}c$. But C$c$ being a mean proportional between Bb and Dd, $\mathrm{C}c = \sqrt{\mathrm{B}b \times \mathrm{D}d}$; therefore $gd - ec = \mathrm{D}d + \mathrm{B}b - 2\sqrt{\mathrm{B}b \times \mathrm{D}d}$. In general, let M, m, represent the quantities of moisture which two portions of air, at different temperatures, can hold in solution, when completely saturated, and let these portions be mixed together in equal quantities, so that the temperature of the mixture may be the mean of the two temperatures, then the quantity deposited will be equal to

$$\mathrm{M} + m - 2\sqrt{\mathrm{M}m}.$$

This quantity, or $gd-ec$, may also be represented geometrically. Thus, join bd, produce Cc till it meet bd in h, and draw hi parallel to cg or AD. Then the triangles beh, hid, are obviously similar and equal, and $eh=id$. Also $gi=ch$, and consequently $gd=eh+hc=ec+2ch$. Therefore the quantity deposited, or $gd-ec=2ch$.

But a deposition of moisture may take place, even though the portions of air are not both saturated before intermixture. The quantity deposited will be less indeed in proportion to the distance of the air from the point of saturation; but still a deposition will take place so long as the moisture contained in both portions at the temperatures B and D, is greater than 2 Cc. This conclusion may also be deduced from the table in the article HYGROMETRY, § 39 Thus let 30° and 50° be the temperatures of the two portions, and let each be 1° from the point of saturation; then the actual quantities of moisture contained in both will be ·002389+·001235=·003624 grs. or ·001912 grs. in one cubic inch. But a cubic inch at 40° (the mean temperature of the mixture,) can dissolve only ·001782 grs.; and consequently ·0003 grs. will be deposited by each cubic inch. See § 93 of the same article.

It appears, from the table now referred to, that when the temperature increases in arithmetical progression, the dissolving power increases somewhat faster than in a geometrical progression. Thus a cubic inch of air at 30°, when saturated, holds in solution ·00127758 gr. and at 50°, ·00246714 gr. If the solving power, therefore, increased in geometrical progression, a cubic inch at 40°, when saturated, ought to dissolve only ·001775 gr.; but, by the table, it is found to dissolve ·001782 gr. being ·000007 gr. greater. This small difference, however, does not at all affect the illustration of the general principle given above.

When different portions of the atmosphere are intermixed, so as to produce a deposition of moisture, the consequence will be, the formation of a cloud. This cloud, from its increased specific gravity, will have a tendency to sink downwards; and, were the lower strata of the atmosphere of the same temperature with the cloud, and saturated with moisture, it would continue to descend till it reached the surface of the earth in the form of rain, or what is commonly called mist. In general, however, the cloud in its descent passes through a warmer region, where the condensed moisture again passes into vapour, and consequently ascends till it reach a temperature sufficiently low to recondense it, when it will begin again to sink. This oscillation will continue till the cloud settles at the point where the temperature and humidity are such, as that the condensed moisture begins to be dissipated, and which is found, on an average, to be between two and three miles above the surface of the earth.

When the condensation of moisture is rapid and copious, there appears to be no reason to doubt, that rain will be immediately produced. Some philosophers, indeed, have maintained that such a condensation, however rapid, never can produce any thing but a cloud, and that the production of rain is the consequence of certain electrical processes that afterwards take place among the minute particles of which the cloud is composed. That electricity is a frequent and a powerful agent in the formation of rain, is extremely probable, but that it is in all cases essential to that phenomenon, appears to us to be a gratuitous assumption, which, however ingeniously supported, is still destitute of satisfactory proof. The well known fact, that the rain which accompanies a thunder storm, is more copious than in any other circumstances, is evidence sufficient that it is frequently modified or increased by the influence of electricity; but this is all that is certainly known upon the subject, and we deem it unnecessary, therefore, to enter on any particular examination of the hypothesis, that the particles of moisture in a cloud are held at a distance from each other by certain electrical atmospheres; and that it is only by the removal of these that the particles unite, and form drops of rain.

It is evident that the mixture of different portions of the atmosphere, to which, in the preceding remarks, we have ascribed the production of rain, must be greatly promoted by opposite currents of wind. These currents are themselves produced, chiefly by the unequal distribution of heat, which disturbs the equilibrium of the atmosphere. When a column of air is heated above the temperature of an adjacent column, it has a tendency to rise, in consequence of its diminished specific gravity, while the colder air flows in to supply its place. Upon this principle, it might be expected, what is found actually to take place, that the colder air, from the poles, is continually displacing the warmer and lighter air of the equatorial regions, thus producing a constant current near the surface of the earth from the pole towards the equator. To supply the place of the air thus carried away from the poles, an opposite current must flow in the higher regions of the atmosphere, from the equator towards the pole, where the air has its temperature reduced, at the same time that the air, by which it was displaced, has its temperature elevated, so that the circulation is constantly kept up. This tendency to an interchange of air between the warmer and colder regions of the globe, combined with the diurnal revolution of the earth, produces that constant current in the neighbourhood of the equator, which is called the trade wind, and which will be considered at greater length under the article Physical Geography.

The wisdom and beneficence which this constitution of things displays, appear in the provision which is hereby made for moderating the extremes of heat and cold in different climates, as well as producing the rain that is necessary for the purposes of vegetation. Were the surface of the globe uniformly smooth, and every where equally susceptible of the impressions of heat and cold, the circulation in the atmosphere would probably suffer no interruption, nor be liable to any irregularities. The variations of the barometer would, in that case, be very small, as they are found to be in the equatorial regions, where the circulation of the atmospherical currents is most steady; and rain would, in all probability, fall only at certain periods, and after long intervals. As the globe, however, is actually constituted, the inequalities of its surface, the different capacities which different parts of that surface have for absorbing or communicating heat, and other disturbing causes, produce frequent and considerable irregularities in the direction and force of the great atmospherical current, and thus give rise to the variety of winds which is found to take place above the 30° parallel of latitude. As the upper current, or that which flows from the equator, is all directed nearly to one point, viz. the pole, its velocity must be increased as it approaches that point, and consequently the effects of the disturbing causes must be greater in the higher latitudes than nearer the equator; an inference which is fully confirmed by observation. The range of the barometer, which may be considered as expressing the amount of the disturbing force, is found to increase with the distance from the equator; but that the quantities of air transported by the two currents are, upon the whole, equal, is obvious from the remarkable fact, that the mean height of the barometrical column, making allowance for difference of temperature and elevation, is nearly the same in all latitudes, where it has yet been observed. It may be supposed, therefore, that the plane which separates the two currents will be nearly at that elevation above the level of the sea, where the barometer would stand at half its mean height, and that here clouds are most likely to be formed, from the contact of two portions of air of different temperatures. This also is confirmed by observation; the height at which the barometer would stand at 15 inches being about 3.4 miles, or nearly the average height of the clouds.

The influence of different currents of air in producing rain, is demonstrated by a great variety of phenomena. In this climate, dry weather generally prevails, either when the atmosphere is in a settled state, or when the wind blows steadily from the same point.

On the other hand, a change of wind is almost always accompanied with rain; and if these changes be frequent and rapid, heavy showers are the consequence. In the tropical climates, the rainy seasons may generally be predicted with the greatest precision, as they are found uniformly to set in with the sun's approach to the zenith, when the winds become variable, or with the change of the monsoon, at which time the heaviest rains fall. In extensive inland plains, where there is nothing to promote the mixture of different currents of air, and where evaporation does not furnish moisture enough to bring the atmosphere to the point of saturation, it seldom rains; while in mountainous countries, especially in the neighbourhood of the sea, it rains frequently.

Where there are so many irregularities to be taken into the account, it seems impossible to calculate with any thing like precision, the quantity of rain that may be expected to fall at any given place in the course of a year. That quantity, indeed, must obviously bear some relation to the moisture which, at the average temperature of the year, can be held in solution in the atmosphere, compared with the yearly evaporation; and, upon this principle, an approximation to the depth of rain for every fifth parallel of latitude, has been given under the article Hygrometry. The results in that table, however, must be considered as excluding the irregularities arising from local circumstances, and cannot, therefore, be expected to give a very near approximation for particular places; but it may be interesting to inquire, how far it coincides with actual observation in our own climate.

From a very extensive collection of facts, Mr. Dalton found that the average annual quantity of rain, for 30 places in England and Wales, amounts to 35.2 inches, the greatest being 67.5 inches, at Keswick in Cumberland; and the least 19.5 at Upminster in Essex. This average, however, is, on various accounts, greatly above the truth. Of the 30 places where the observations were made, 2 are in Cumberland, 3 in Westmoreland, and 5 in Lancashire; the counties where, of all others, the quantity of rain might be expected, and is actually found to be the greatest. Mr. Dalton indeed has made an allowance for the excess arising from this circumstance, by taking a mean of the different places in the same county, and then an average for all the counties, which reduces the general mean from 35.2 to 31.3 inches; but we are inclined to think that even this is too high an average for the whole of England and Wales. Of the 20 counties where the places referred to by Mr. Dalton are situated, 13 are maritime; yet notwithstanding this great proportion of counties where the atmosphere is most likely to be humid, there are 16 of the whole 30 places, where the quantity of rain is below 30 inches. Had the observations been made at equal distances over the whole country, it is probable that the general mean would be considerably below this last quantity. Taking the mean latitude of England and Wales at 52½°, the average yearly rain by the table alluded to above, should be 23.5 inches.

We have found from our own observations, that the annual quantity of rain, in latitude 56½°, and in a situation not likely to be much affected by local circumstances, is, on an average of 6 years, commencing with 1813, 23.7 inches; and leaving out the years 1817 and 1818, when the quantity of rain was unusually great, the average is 21.5. By the table it should be 21. At another place, under the same latitude, but in the immediate vicinity of a hill 6 or 7 hundred feet in height, the average depth of rain for the same six years, is about 25.5 inches.

A question has sometimes been agitated respecting the comparative quantities of rain, that fall at the summit and base of a hill. It appears from experiment, that a rain gage, placed near the surface of the earth, collects a greater quantity of rain than one elevated above it, and the difference has been generally ascribed to the influence of the wind. It has also been supposed, that independent of this cause, the quantity must be greater below than above, owing to the gradual accumulation, and consequent enlargement of the drops in their descent through the atmosphere. Now there are only two cases in which it appears that this can take place; either when the atmosphere throughout is saturated with moisture, or when the temperature of the rain is so low, as to reduce the air with which it comes in contact in its descent, to the point of deposition. There is reason to doubt, however, whether these cases occur generally or even frequently. We have often observed the hygrometer during a heavy and even long continued rain, indicate from 5 to 10 degrees of dryness, so that instead of increasing, there is reason to believe that the drops sometimes diminish on their approach to the earth. But whatever may be the cause of the difference between the indications of two rain gages placed at different altitudes above the same plane, there can be little doubt, that the quantity of rain which falls on the summit of a hill, is greater than what falls at the base, and that the difference is easily accounted for from the well-known fact, that the nimbus or rain-cloud, as well as fogs and mists, is often attracted by mountains, and is seen to rest upon them, while there is little or no rain below. This, of course, supposes, that the hill is of considerable height and magnitude, and that the observation in this case holds true is fully established by the following facts.

In the neighbourhood of Kinfaun's Castle, a rain-gage is placed on the summit of a hill, 600 feet above the level of the sea, and another in the garden at the base of the hill, about 20 feet above the sea. The following are the annual results of the two for five years:

Years.	Hill Gage.		Garden Gage.	
	In.	Dec.	In.	Dec.
1814	33	.84	20	.05
1815	45	.70	24	.20
1816	52	.43	24	.95
1817	44	.40	31	.01
1818	31	.10	28	.07
Means.	41	.49	25	.66

No part of the above difference can be ascribed to any thing in the situation of the garden gage but its being lower down. It is fully exposed to the rain; and, as the best proof of this, it is only necessary to remark, that its average amount for six years is about two inches greater than that of another, situated in an open country, at the distance of about a mile.

When clouds are formed at an elevation, where the temperature is below 32°, the particles of moisture become congealed, and fall down in the form of snow or hail. If the temperature of the lower regions of the atmosphere be much above 32°, it will sometimes happen that the snow is again dissolved before it reaches the earth; but hail, from its greater solidity, as well as more rapid descent, frequently arrives at the ground in its congealed state even during the summer months. There can be no doubt that the moisture, of which hail consists, had been collected into large drops of rain previous to its being congealed; and Mr. Leslie has proposed an explanation of the manner in which the congelation takes place. "If we examine," says he, "the structure of a hail-stone, we shall perceive a snowy kernel incased by a harder crust. It has very nearly the appearance of a drop of water suddenly frozen, the particles of air being driven from the surface towards the centre, where they form a spongy texture. This circumstance suggests the probable origin of hail, which is perhaps occasioned by rain falling through a dry and very cold stratum of air." He then proceeds to point out a method of putting this theory to the test of experiment; but, in fact, it has been already confirmed, by the process of freezing water under the receiver of an air-pump.

From all that has been stated on the formation of clouds, and the production of rain, we are naturally led to remark, that however important may be the facts which meteorological researches are in time likely to disclose, there is but little probability of our ever being able to predict, with any thing like certainty in every case, the approach of the most common and familiar of all atmospherical phenomena. By the extended use of the hygrometer, we may discover a great deal more than we yet know of the state of the atmosphere near the surface of the earth; but we cannot from this infer any thing with certainty regarding the processes that are going on in the region of the clouds, or anticipate the nature and extent of future changes in the weather. We have repeatedly remarked, in the course of our observations, a heavy and long continued fall of rain, commencing a few hours after the hygrometer had indicated an unusual degree of dryness in the lower atmosphere; and, on the contrary, the air passing from a state of almost complete saturation to great dryness without any rain at all. The barometer is the only instrument by which distant changes in the atmosphere can be detected; but as its fluctuations merely give us notice of variations in the weight of that fluid, they do not necessarily indicate the approach of rain. In fact, the only information that this instrument gives us, is the amount of the disturbance that has taken place in the equilibrium of the atmosphere. When the mercurial column, therefore, sinks below its mean height, all that we can directly infer is, that some change has happened, or will soon happen, in the force or direction of the wind; but as this is likely to bring different or opposite currents into contact, it may naturally be expected that rain will be the consequence. It is in this way only that the fall of the barometer is an indication of rain. It may be observed, too, that the intermixture of different portions of the atmosphere, in such circumstances as to produce rain, sometimes takes place, not at the first disturbance, but at the subsequent restoration of the equilibrium; and we find accordingly, that, on some occasions, the barometer, after being depressed below its mean height, has begun again to rise before the rain commences. To illustrate these remarks, we shall extract from our register the greatest falls of rain that have taken place since 1815, with the corresponding state of the barometer, and the relative humidity of the atmosphere, at 10 morning and evening, confining ourselves to those cases in which the quantity of rain amounted to an inch in 48 hours.

The mean height of the barometer, from the beginning of 1815 to the middle of 1819, was 29.650, and the mean relative humidity, at 10 morning and evening, about 80. The average of the barometer in the above table is 29.475, and the relative humidity 88.5. The table, however, presents many anomalies from any general inference that might be drawn from these facts. Thus, on the 7th of July, 1816, the barometer was almost stationary at a point rather above than below the mean height, not only on that but also on the preceding day, though the quantity of rain amounted to an inch in 24 hours. It may be alleged, indeed, that the wind on that occasion blew from the east; and as an east wind, in this country, generally raises the barometer two or three tenths above its mean height, the altitude of the mercury on that day was as far below what it ought to have been, as the average of the preceding table is below the average of the whole period. There are cases, however, where this explanation does not apply. On the 9th and 10th of June, 1817, and the 26th and 27th of July, 1818, upwards of an inch of rain fell; while the barometer, with a west wind, stood in the one case very little below, and in the other considerably above, the mean height. It the former case, indeed, the mercury had sunk on the 8th to 29.4, but in the latter it was almost stationary for several days.

But the most remarkable fact in the above table is, the unusual degree of dryness that sometimes existed in the lower atmosphere immediately before a considerable fall of rain. Thus, on the 26th of May, 1817, the relative humidity was 19, and, on the 20th of June, 1819, it was 38 degrees below the ordinary annual mean, though a few hours afterwards rain commenced, and in both cases exceeded an inch. It would thus appear, that the formation of rain sometimes takes place at a great height above the surface of the earth, and is altogether independent of the quantity of moisture that exists in the lower strata of the atmosphere.

But though it may be difficult to assign any satisfactory reason for the particular facts now stated, it seems to be sufficiently clear, that in general the quantity of rain that falls at any given place in the course of a year bears a certain relation to the moisture which can be held in solution by the atmosphere, at the average temperature of that place; and that the depth of rain, therefore, must depend in some degree on the quantity of evaporation. The relation between these quantities, as deduced from the law of aqueous solution in the atmosphere, may be seen from the table formerly alluded to in section 99 of the article Hygrometry, containing the quantity of rain for every 5° parallel of latitude, compared with another table in section 51 of the same article, shewing the daily and yearly evaporation for the same parallels. We have already seen that the former of these tables gives an approximation to the depth of rain as found by actual observation; and though it is difficult, perhaps impossible, to measure with accuracy the quantity of evaporation from the surface of the ground, the most satisfactory experiments on the subject give results coinciding very nearly with the quantities given in the table of evaporation.

From observations made by Dr. Dobson at Liverpool, for four years, commencing with 1772, it would appear that the annual evaporation from the surface of the water in that latitude, amounts to 36.78 inches. There can be little doubt, that where the water in the evaporating basin is freely exposed to the influence of the sun and wind, or even of the latter alone, the quantity evaporated in the course of a year may amount to 36 or 37 inches. This, however, is obviously a much greater quantity than could be dissolved by a column of the atmosphere, whose base is equal to the exposed surface, because in the case of even a moderate wind, the original rate of evaporation is kept up by a constant succession of new columns, whose bases are every instant coming in contact with the surface of the water. It must be greater also than what is actually evaporated from the earth; for though the latter is exposed to the influence of both the sun and wind, the surface in a short time becomes dry, and the moisture is not drawn up from below so quickly as to yield a supply equal to that afforded from the surface of water. There is reason, however, to believe, that the actual evaporation from the ground, in ordinary cases, approaches nearer, than that from an exposed evaporating vessel, to the true quantity of evaporation at any given place; meaning by this, the quantity which the atmosphere at that place would dissolve, were the whole surface of the globe covered with water. The ground indeed after a time ceases to supply moisture as quickly as the air is capable of dissolving it; but were the surface continually wet, the dissolving power of the air, and consequently the rate of evaporation, would diminish, and perhaps as rapidly as the supply of moisture from the earth is found to do in the present state of things. But the readiest, and perhaps, after all, the most accurate estimate of evaporation, is found by placing the common evaporating basin, or atmometer, in a situation out of the reach of the sun's direct influence, and sheltered as much as possible from the wind. The results obtained in this way, appear from the following facts to coincide nearly with those of experiments made to ascertain the actual evaporation from the earth.

By a vessel situated as above described, we found the annual evaporation in latitude $56\frac{1}{4}$°, for the last two years, to be as follows:

1817 . . . . 20.991 inches
1818 . . . . 20.056

being a mean of 20.523. The amount from September 1818 to August 1819 inclusive, is 20.765. The annual evaporation, therefore, may be stated at 20.6 inches.

From the experiments instituted by Mr. Dalton in 1796, and which have been detailed under the article Evaporation, it was found that the quantity evaporated from the ground, on an average of three years, amounts to 25.158 inches. There is reason to believe, however, from certain circumstances in the mode of conducting the experiments, that this quantity is rather above than below the truth; but even admitting that there was no source of fallacy in the observations, the result, making allowance for difference of latitude, which may be about 3°, coincides very nearly with those given above. Both results approximate to the quantities deduced by Mr. Anderson from the law of aqueous solution. By the table of evaporation formerly alluded to, the quantity corresponding to latitude $56\frac{1}{4}$° is 22.35, and for latitude 53° 24.54, being 1.75 greater in the one case, and .62 less in the other than what is found by actual observation.

It may perhaps appear at first sight, that the near approximation to equality between the quantity of rain and that of evaporation, which some of the preceding remarks seem to imply, is inconsistent with the universally received opinion respecting the origin of springs. If the evaporation be as great, or the depth of rain as small as has been stated, it may be alleged that there is not a sufficient supply of water to keep permanent springs and rivers continually flowing. It is to be remembered, however, that the quantity of rain that falls on mountains, and elevated tracts of country, greatly exceeds what is deposited in plains, or what would fall if there were no mountains; and that it is chiefly from the latter that springs and rivers derive their supply. Mr. Dalton has calculated, that the quantity of water annually discharged into the sea by all the rivers in England and Wales, amounts only to about thirteen inches of rain over the whole surface; and when it is considered that the water deposited on mountains very quickly arrives at rocks, which, from their stratified position, convey it with little waste to the point where it is to issue in a spring, there seems to be little difficulty in conceiving, that the superabundant moisture which falls there is fully adequate to the supply. There is, no doubt, in all such calculations as those of Mr. Dalton, a vagueness and want of precision; but his estimate of the quantity of water annually discharged by all the rivers in England, is just as likely to be above as below the truth.

Another phenomenon, intimately connected with the subject now under consideration, and which has of late occupied no small share of the attention of philosophers, is the formation of *dew*. From a very early period, it has been observed that dew is always most copious during clear and calm nights; and an idea seems also to have long prevailed, that it is accompanied with a reduction of temperature. The late Dr. Wells, however, was unquestionably the first person who proposed a distinct and satisfactory theory upon the subject. That gentleman has shown, by a great variety of well-conducted and accurate experiments, that dew is never formed upon any substance till the temperature of that substance has been reduced below the temperature of the surrounding atmosphere; and has consequently proved, that the cold which accompanies dew, precedes instead of following the production of that fluid. This indeed might have been inferred from the well-known fact, that vapour, in passing from the aeriform to the fluid state, gives out instead of absorbing caloric; and the formation of dew, therefore, so far from increasing, must diminish the cold of contiguous bodies. But Dr. Wells has also proved, in a manner equally satisfactory, that the surface of the ground, as well as other bodies, has its temperature reduced below that of the atmosphere, by being freely exposed to the clear sky, and that whatever screens it from this exposure, prevents the reduction of temperature. Thus he found, that on clear and calm nights, a thermometer, in contact with the grass, frequently stood from 7° to 12°, and on one occasion 15° lower than another situated four feet above the surface; and of two thermometers which were both in contact with the grass, one being freely exposed, and the other sheltered by a screen of pasteboard, the former sometimes indicated a temperature 10° below the latter. In cloudy weather, and particularly when there was wind, he seldom observed much difference between the temperature of the grass and that of the air; but, in such weather, a clear interval seldom failed to produce a great reduction of temperature on the surface of the ground, while a passing cloud over a clear sky generally raised the thermometer on the grass several degrees. Dr. Wells observed farther, that when bodies, which had been equally exposed to the air, were examined at the same time, those which had suffered the greatest reduction of temperature had also collected the greatest quantity of dew; and that substances which had been exposed to the sky were uniformly more dewed than those which had been screened. In proof of this, we shall give the result of one experiment, among many that might be produced, and which appears to be perfectly satisfactory.

"I bent a sheet of pasteboard," says Dr. Wells, *Essay on Dew*, p. 15, 1st edition, "into the shape of a house roof, making the angle of flexure 90 degrees, and leaving both ends open. This was placed one evening with its ridge uppermost upon the same grass plat, in the direction of the wind, as well as this could be ascertained. I then laid ten grains of wool on the middle of that part of the grass which was sheltered by the roof, and the same quantity on another part of the grass plat fully exposed to the sky. In the morning, the sheltered wool was found to have increased in weight only two grains, but that which had been exposed to the sky sixteen grains.

From these experiments, repeated in a great variety of ways, Dr. Wells deduced the following theory of the production of dew. On the commonly received and well-established fact, that bodies have a tendency to throw off caloric by radiation to other bodies, whose temperature is lower, he supposes that the earth is continually radiating its heat to the high and colder regions of the atmosphere; that, in the day time, the effects of this radiation are not sensible, being more than counterbalanced by the greater influx of heat from the direct influence of the sun; but that during the night, when the counteracting cause is removed, these effects become sensible, and produce the reduction of temperature above stated, unless where clouds interpose, which operate as a screen in arresting the rays of heat. Dr. Wells seems to think, that the interposition of clouds operate not only as a screen in preventing radiation from the earth, but by actually radiating heat back to the ground, and thus restoring a portion of what had been formerly abstracted. This, we apprehend, may possibly take place when the clouds are low and dense, to which indeed Dr. Wells's remark chiefly applies; but, in general, their elevation is such, that their temperatrue must be lower than even the reduced temperature of the ground. But however this may be, the cold produced by radiation to a clear sky is sufficient to account for all the phenomena of dew. We have already seen, that the mean point of deposition in the atmosphere is about 6° below its mean minimum temperature, and that below this point it is no longer capable of holding its moisture in a state of solution. When the ground, therefore, is cooled down from 7° to 12° below the atmosphere, the portion of the latter in contact with the surface will in general be reduced below the point of deposition, and must consequently part with a portion of its humidity, the quantity deposited being proportional to the reduction of temperature, and the previous state of the air with regard to moisture. It appears accordingly from Dr. Wells's experiments, what might be inferred from the theory, that though of two similar substances examined at the same time, the coldest was always the most dewed, it did not uniformly happen, that on different nights, or even at different times of the same night, the quantity of dew was proportional to the reduction of temperature alone. "Thus during two nights," says Dr. Wells, p. 43, "on which grass was 12° or 14° colder than the air, there was little dew; while on the night which afforded the most copious dew ever observed by me, the cold possessed by the grass beyond that of the air was for the most part only 3° or 4°." It is deeply to be regretted, that in none of his experiments did Dr. Wells employ Leslie's hygrometer, the state of which, at the time of his observations, could not have failed to give them a precision which they can never otherwise possess.

The opinion which has sometimes been entertained, that dew is entirely produced by vapour emitted from the earth and vegetable substances, has been satisfactorily refuted by Dr. Wells, at least in so far as he has demonstrated, that a great proportion of it is deposited from the atmosphere. He has also examined, at considerable length, some of the objections that may be urged against his theory, and has thus been led to discuss various collateral subjects of considerable interest. But for these we must refer to the treatise itself. We would only observe, that the principle which he has assumed as the foundation of his theory, affords a satisfactory explanation of all the phenomena accompanying the production of dew, and that none of the apparent anomalies hitherto observed are sufficient of themselves to set that principle aside. It is in the adoption of this principle, indeed, that the chief merit of Dr. Wells consists, as many of the facts which he states had been previously made known by the experiments of Mr. Six of Canterbury, and Dr. Wilson of Glasgow.

When the *Essay on Dew* first made its appearance, it excited considerable interest in the scientific world, and for some time the accuracy of the theory there advanced seemed to be generally admitted. Of late, however, a very formidable attack has been made on the fundamental principle of that theory, and from a quarter which renders it particularly deserving of notice. Mr. Leslie, after having assigned to Dr. Wells "the merit of being the first who distinctly attributed the formation of dew to the previous cold induced on the ground from the aspect of the sky," and admitted that "this cooling of substances from exposure is at least one great source of dew," proceeds to express his regret, "that the explication of this primary phenomenon should have been sought for from the very loose, cumbrous, and visionary hypothesis, concerning what is gratuitously called *radiant heat*;" an hypothesis which he considers as "repugnant to all the principles of sound philosophy," and as "obtaining favour only from the blind admiration which the multitude are prone to entertain for whatever lulls the reasoning faculty, and appears cloudy and mysterious." The principle which Mr. Leslie proposes to substitute for radiant heat, in explaining the phenomena observed by Dr. Wells, is that of cold pulsations from the higher regions; but to do justice to the hypothesis, it will be necessary to state it in the author's own words. After explaining the diffusion of heat through the atmosphere, in a manner similar to the propagation of sound, he thus proceeds: "But the same pulsatory system will enable the atmosphere to transmit likewise the impressions of cold. The shell of air adjacent to a frigid surface becoming suddenly chilled, suffers a corresponding contraction, which must excite a concatenated train of pulsations. This contraction is followed by an immediate expansion, which withdraws a portion of heat from the next succeeding shell, itself now in the act of contracting; and the tide of apparent cold, or rather of deficient heat, shoots forwards with diffusive sweep."

Now it must appear obvious, we think, that upon this principle the frigorific pulses which Mr. Leslie supposes are showered down from the higher regions, never can communicate to the earth a greater degree of cold than they had previously communicated to the atmosphere. When the last pulsation reaches the surface of the ground, it will deposit its load of cold, if we may use such an expression, or abstract from the earth a quantity of caloric proportional to its reduction of temperature below that of the earth; but if the latter be the colder of the two, instead of abstracting, the shell of air will deposit heat, and tend to bring the ground to the same temperature with itself. The moment that the lowest film, or indefinitely small wave of air, comes in contact with a colder surface, it is precisely in the same circumstances with the highest one where the pulsation commenced; and should the temperature of the ground, therefore, be reduced by any means below that of the atmosphere, a concatenated train of pulsations ought, upon Mr. Leslie's principles, to commence at the surface of the earth, and proceed upwards till they arrive at a still colder region. Nor will it at all remove this objection, to say, that the pulsations from above more than counteract those from below, in consequence of the former being at a lower temperature than the latter. Admitting that the descending wave is the colder of the two, and not only arrests the progress of the other upwards, but actually propels it back again towards the earth, it still remains to be explained, how the surface of the ground comes to have its temperature reduced below that of the body by which it it is cooled, as was found to be the case by Dr. Wells and other observers. According to Mr. Leslie's theory, the atmosphere is not merely the medium by which the cold pulsations are conveyed, without having its own temperature affected by them. These pulsations are, in fact, the contractions which take place in the atmosphere itself, in consequence of the successive abstraction of caloric from each indefinitely thin film or stratum, so that the degree of cold which ultimately reaches the surface of the ground, can be nothing more than that to which the intermediate strata of the atmosphere had been previously reduced. If it be said, that these cold pulsations reach the earth without expending their cooling energy on the atmosphere, then we are at a loss to see any thing else in this than the "vulgar and unphilosophical" principle of *radiation*, or in what respects Mr. Leslie's theory differs from that of Dr. Wells, except that the latter ascribes the cold induced on the ground to the radiation of heat upwards, while the former explains it by the radiation of cold downwards. In whatever light Mr. Leslie's theory be viewed, it seems to be liable to much stronger objections than the one on which he has passed so severe a censure, and to which of the two the epithets of "cloudy and mysterious" may be justly applied, it is not very difficult we think to decide.

But it may perhaps be alleged, that the reality of frigorific pulses from a clear sky is established by the indications of an instrument lately constructed by Mr. Leslie, and to which he has given the name of Æthrioscope. This instrument is nothing more than the differential thermometer, placed in the hollow of an oblong spheroidal cup of brass or silver, having the sentient ball in the axis, and the other, which is covered with silver leaf, lodged in the cavity, and nearly in contact with the side of the cup. When the instrument in this state is freely exposed to the sky, the ball in the focus of the cup suffers a diminution of temperature, the enclosed air is contracted, and the liquid rises in the tube towards the ball, indicating a difference of temperature between the two balls, which in some cases amounts to 50 millesimal degrees. This effect is ascribed by Mr. Leslie to "an impression of cold shot downwards from the higher regions; but the phenomenon is just as easily accounted for on the principle adopted by Dr. Wells. The radiation of heat to the sky, from the sentient ball of the Æthrioscope, is augmented by that ball being placed in the focus of a metallic cup, which is itself radiating heat towards the same quarter, exactly as in the case of a heated body placed in the focus of a metallic reflector. Were the ball of the Æthrioscope exposed by itself, it would radiate heat only from the side directed towards the sky; but by being placed in the focus of the cup, radiation goes on from every point of its surface. This instrument therefore furnishes no additional support to Mr. Leslie's theory, nor does it at all militate against the commonly received opinion regarding the radiation of caloric. See our article COLD.

Various circumstances besides those already mentioned, occurred to Dr. Wells in the course of his experiments, which tend to confirm his theory of the production of dew. Thus he found that substances, as metals for example, which readily receive heat by conduction, but which radiate slowly, were, *ceteris, paribus*, less dewed than bodies possessing different qualities. He found also that grass, on a clear and still night, was uniformly colder than a gravel walk, evidently owing to the different quantities of heat which they received by conduction from the interior of the ground; and that on the same principle filamentous and downy substances become colder than all others. The influence of wind in preventing a reduction of temperature on the surface of the earth, even when the sky is clear, he ascribes not to its diminishing the quantity of radiation, but to its bringing successive portions of warmer air in contact with the ground, so that no dew can be formed till the whole of the air thus agitated is cooled down to the point of deposition. The same cause will account for less dew being deposited on mountains than on plains.

Some philosophers have ascribed the cold observed on the surface of the ground to evaporation, and there can be no doubt that, in certain circumstances, a considerable reduction of temperature may in this way be produced. We have frequently observed congelation going on in moist places during a brisk wind, while the temperature of the atmosphere at the height of a few feet was as high as 40°, and have more than once seen an icicle forming at the bulb of a moistened thermometer, while a contiguous dry one indicated a temperature of 38° or 39°. It is impossible, however, upon this principle, to account for many of the phenomena observed by Dr. Wells. If the cold were produced by evaporation alone, the difference between the temperature of the ground and that of the atmosphere near it, would diminish as the air became moist, and would disappear altogether when the latter was completely saturated. But the cold observed by Dr. Wells continued long after a deposition of moisture had taken place, and when not only evaporation must have ceased, but caloric must have been disengaged or become sensible, by the vapour passing into a liquid state. Besides, evaporation could have nothing to do with the reduction of temperature observed on substances exposed in a state of dryness, and not in contact with the earth.

When the temperature of the ground, after the deposition of moisture has taken place, is at or below 32°, the dew is congealed, and becomes *hoar frost*. According to the experiments detailed above, this may happen when the temperature of the atmosphere, a few feet above the surface, is considerably above 40°. We have often observed a copious hoar frost after a clear and calm night, though the minimum temperature, as indicated by a self-registering thermometer, had not been lower than 41° or 42°. The theory advanced by Dr. Wells satisfactorily explains this curious phenomenon, as well as the practical utility of the method frequently adopted by gardeners for preserving tender plants, by laying or suspending over them any covering, however thin, that serves to screen them from exposure to a clear sky.

We cannot conclude this article without expressing our regret, that the application of the principles developed by the researches of Leslie, Anderson, and Wells, has hitherto so seldom found a place in meteorological journals. To the laborious experiments and profound investigations of these eminent individuals the science has been deeply indebted; but it still remains for meteorologists to bring these discoveries to the test of daily observation, in order to confirm or correct the principles on which they are founded. In illustration of this remark, as well as of some other observations that have been made in the course of this article, we submit the following plan of a meteorological journal, which, though as extensive as any we have yet seen, still admits of some important additions and improvements.

Plan of a Meteorological Journal.

Year.	Thermometer.									Barometer.										
Mon.	Extr.		10.		Mean of			Daily Range.	Temp. spring water.	10 Mor.		10 Even.		Mean.		Day.		Night.		Range in 24 hours.
Date.	Max.	Min.	Morn.	Even.	Max. and Min.	10 and 10.	Both.			Temper.	Pressure.	Temper.	Pressure.	Temper.	Pressure.	Elevation.	Depression.	Elevation.	Depression.	

In examining meteorological tables, the difficulty of perceiving at once the extent of the fluctuations that take place in the temperature and pressure of the atmosphere is a frequent and just subject of complaint; and to remove this difficulty, a very simple expedient has been proposed, and is now frequently adopted. This method is represented in Plate CCCLXXIV. Fig. 10, where the horizontal lines denote the degrees of the thermometer, and the spaces between the vertical lines represent the days of the month. The extreme elevations and depressions of the instrument, or the points at which it stands at the hours of observation for every day, are marked on the diagram, and the line joining these points exhibits at one view the fluctuations of temperature. A similar diagram is employed to represent the elevations and depressions of the barometer. The necessity of this method however is, in some measure at least, superseded by entering in a separate column, as in the above plan, the daily range of both instruments. That of the thermometer is found by subtracting the maximum from the minimum, and an *approximation* to that of the barometer, by taking the difference between the observations at 10 morning and evening of the same day, which is entered in the 7th or 8th column, according as the mercury has risen or fallen, and also the difference between the observations at 10 on the evening of the one day and 10 on the morning of the following day, which is entered in the 9th or 10th column. The sum of these two differences is then carried to the last column, as the amount of the barometrical range for the whole twenty-four hours.

Hygrometer.																Wind.		Moon			Weather.	
Amount.		Leslie's.			Anderson's Formula.											By the clouds.		Mean Time.			General Remarks.	
					Point of Depos.			Quant. Moisture.			Rel. Humidity.											
Rain	Evaporation.	10 Morning.	10 Evening.	Mean.	10 Morn.	10 Even.	Mean	10 Morn.	10 Even.	Mean.	10 Morn.	10 Even	Mean.			Force.	Direction.	Phases.	Morning.	Evening.	Morning.	Evening.

The particulars in the above plan, which, as far as we know, are not to be found in any other table yet made public, are the results of Anderson's formula, as already explained, viz. the point of deposition, or the temperature at which the atmosphere would begin to deposit moisture; the actual quantity of moisture contained in 100 cubic inches of air, expressed in decimals of a grain; and the relative humidity, or quantity of moisture expressed in hundredths of what would produce complete saturation. In addition to these, however, it would be desirable, we think, to ascertain the following facts.

1*st*, The lowest point to which the temperature of the ground sinks during the night, and which might be found by exposing a minimum thermometer on the grass, and recording the result in the morning; and

2*dly*, The greatest depression of the hygrometer, both at the surface of the ground and a few feet above it, which might be ascertained by the self-registering hygrometer formerly explained. Were these instruments generally employed, every meteorological journal would exhibit a series of experiments, which could hardly fail both to give greater precision to the discoveries that have already been made, and to extend the boundaries of a science in which, from the want of accurate and uniform registers, there are still so many desiderata. See Arist. *De Meteor.* Arat. Dios. De Luc. *Idées sur la Meteorologie.* Forster *On Atmospheric Phenomena.* *Philosophical Transactions, Lond. and Edin* Leslie *On Heat and Moisture.* Playfair's *Outlines of Natural Philosophy.* Dalton's *Meteorology.* Wells *On Dew.* And our articles ATMOSPHERICAL CLOCK, BAROMETER, COLD, EVAPORATION, HYGROMETRY, PHYSICAL GEOGRAPHY, PNEUMATICS, THERMOMETER. &c. APPENDIX.

While the preceding article was preparing for the press, we were carrying on a series of observations with the sympiesometer, suspended in the same apartment with a very delicate mountain barometer. It may perhaps be gratifying to some of our readers to see the result of these, at the same time that they will shew on what grounds we formerly ventured to conjecture, that there might be something like absorption between the gas and the oil. Our observations commenced on the 4th of September, and were made generally twice a-day, with the most scrupulous attention to accuracy. We shall confine ourselves, however, to the observation at 10 in the morning.

Comparison of the Sympiesometer with the Mountain Barometer.

It appears, from the above table, that the difference between the barometer and sympiesometer, which is always on the same side, generally increases as the temperature and pressure are diminished, though there are also instances in which this does not hold. This fact sufficiently explains what was observed by Lord Gray, and formerly noticed, that the difference between the two instruments, after progressively increasing for a time, began gradually to diminish; but it does not appear so easy to explain the fact itself. It could easily be shewn, indeed, from the law which regulates the elasticity and expansion of permanently elastic fluids, that however accurately the extreme points of the scale may be determined, if the intermediate space be divided into equal parts, the indications of the instrument cannot exactly coincide with those of the barometer under all pressures, and at all temperatures; but whether the error arising from this cause be sufficient to account for the differences in the above table, we shall not at present inquire. We would only remark, that though, in its present state, the sympiesometer cannot perhaps be relied on as an accurate measure of the weight of the atmosphere, its utility as a marine barometer is unquestionable. The instrument of this kind most valuable to the navigator, is that which is least affected by the ship's motion, and at the same time most sensible in indicating changes in the pressure of the atmosphere, without any regard to its absolute weight. With respect to the former, the superiority of the sympiesometer is too obvious to require being pointed out; and, with regard to delicacy, our own observations would lead us to infer that it is also superior to the mercurial barometer.

METHODISTS. A college of physicians who are said to have arisen at Rome in the days of Nero, and to have lasted 300 years, were called Methodistæ, from the regimen under which they put their patients. In the church of Rome, a species of polemical divines are called Methodists. In England the term Methodist, and Methodistical, is applied by way of sarcasm to the stricter professors of religion, although they may be regular members of the church of England, and never enter the doors of any conventicle. This use of the term is scarcely known in Scotland.

METHODISTS, as the distinctive appellation of a religious community, is now universally understood as designating the followers of the famous Mr. John Wesley. We indeed hear and read of *Calvinistic* and *Arminian* Methodists, the former being the followers of the Rev. George Whitefield, and the latter, of Wesley: but for many years the general term Methodist, as marking a sect of religionists, applies to those only who adopt the doctrine and discipline introduced by Mr. Wesley and his coadjutors. The Calvinistic Methodists or Congregationalists bear a near resemblance to the Puritans of a former age, being, generally speaking, deeper divines, and more systematically correct in their doctrinal opinions; for though they have no formula or creed, professedly, yet the books approved among them, and the account which members on admission give of their faith, plainly mark them as Calvinists at least of the Sublapsarian kind. But this article regards the Methodists as a distinct body, closely affiliated and known to each other in every quarter of the globe. In November, 1729, Mr. John Wesley being then a Fellow of Lincoln College, Oxford, Mr. Charles Wesley his brother, Mr. Morgan, Commoner of Christ Church, and Mr. Kirkman of Merton College, set apart some evenings for reading the original Scriptures and prayer. Some time after they were joined by Mr. Ingham of Queen's College, Mr. Broughton of Exeter, and Mr. James Hervey; and in 1735, by the celebrated Mr. George Whitefield. They soon began to leave occasionally the more private fellowship meeting, to visit the prisoners in the castle, and the sick poor in the town. They also instituted a fund for the relief of the poor, to support which they abridged all superfluities, and even many of the comforts of life. Their private meetings became more and more of a religious character. They observed the fasts of the ancient Church every Wednesday and Friday, and communicated once a-week. "We were now," says Mr. Wesley, "fifteen in number, all of one heart and of one mind." Their strict deportment soon attracted the attention of the college censors and students, who branded them with many opprobrious epithets, such as Sacramentarians, the Godly Club, and afterwards *Methodists.* The sneers of the young men they seem to have regarded little; but when some of the seniors of the University were offended, Mr. John Wesley wrote to his father, the venerable Rector of Epworth, and to other gentlemen of learning and piety, for advice. The following sentences from his father's answer will shew his spirit. "And now as to your designs and employments, what can I say less of them than *valde probo*; and that I have the highest reason to bless God, that he has given me two sons together at Oxford, to whom he has given grace and courage to turn the war against the world and the devil, which is the best way to conquer them; they have but one more enemy to combat with, *the flesh.* I think I must adopt Mr. Morgan to be my son with you, and your brother Charles; and when I have such a ternion to prosecute that war wherein I am now '*Miles Emeritus*, I shall not be ashamed when they speak with their enemies in the gate.' When I was an under graduate I visited those in the Castle there; and reflect on it with pleasure to this day. Walk as prudently as you can, but not fearfully, and my heart and prayers are with you." Whatever effect obloquy might have upon some of the members of this select class, Mr. John Wesley, as well as his brother, and several others, remained unshaken. He puzzled his opponents with questions concerning the reasonableness of his conduct. He did more; he confounded them by an uniform regularity of life, and an astonishing proficiency in his studies. Mr. Morgan, one of the most active members, was soon after this removed by death; occasioned, according to the representation of enemies, by fasting and excessive austerities; a very uncommon cause of dying at Oxford, or any where else. His character was drawn by Mr. Samuel Wesley, junr. in a poetic tribute to his memory, under this text, from the book of wisdom, "We fools accounted his life madness." In the spring of 1735, Mr. John Wesley was called to attend his dying father, who desired him to present to Queen Caroline, a book he had just finished. Soon after his return to Oxford, he went to London on this account, where he was strongly solicited by Dr. Burton, one of the trustees for the new colony at Georgia, to go there to preach to the Indians. At first he peremptorily refused. He particularly mentioned the grief it would occasion to his widowed mother. The case being referred to her, she is said to have made this reply: "Had I twenty sons, I should rejoice that they were all so employed, though I should never see them more." His way appeared now plain; and he made arrangements for this enterprize. On Tuesday, October 14, 1735, he set off from London for Gravesend, accompanied by Mr. Ingham, Mr. Delamotte, and his brother Charles, to embark for Georgia. There were six-and-twenty Germans on board, members of the Moravian church, with whose Christian deportment Mr. Wesley was much struck, and immediately set himself to learn the German language, in order to converse with them. The Moravian Bishop, and two others of his society, began to learn English. He now began to preach extempore, which he afterwards made his constant practice during his life, and yet he wrote much.

The piety and devotion which Mr. Wesley and his companions manifested during the voyage was highly commendable, and indicated a becoming impression of the importance of their undertaking; but, owing to some disagreeable circumstances, Mr. John Wesley returned to England without having made much progress in the proposed object, and was succeeded by his valued friend Mr. George Whitefield, who arrived at Savannah on the 7th May 1738, and was received by Mr. Delamotte, and many of Mr. Wesley's hearers. It may be proper to notice the success which attended Mr. Whitefield's labours in this quarter of the globe. He laboured with great zeal, and was honoured to be useful. He returned to England in the close of the same year to receive priest's orders. On his return to America in 1739, he landed at Philadelphia, and immediately began his spiritual labours, which he continued as he passed through the colonies of Virginia, Maryland, and North and South Carolina, being attended by considerable audiences. Upon his arrival at Savannah, he found the colony almost deserted, which moved him to carry into effect his scheme of building an orphan-house, which he had the happiness to see completed through his exertions, and the liberal donations of his friends. Upon his third visit to the western continent, he took a voyage to the Bermudas Islands, where his ministry was successfully attended, and some contributions made for his orphan-house at Savannah. Upon his sixth voyage to Georgia, he received the thanks of the governor and principal people, for the advantage which the colony had derived from his benevolent exertions, a circumstance which tends greatly to vindicate the character of this singular man, from the very unjust reproach of avarice which was frequently thrown upon him. In 1769, he made his 7th and last voyage to America; but, although his labours were so extensive, he formed no separate congregations. In the intervals of his visits to America, he frequently made tours to Scotland and Ireland, where he attracted numerous assemblies, and always made a powerful impression by his eloquence; but having differed in doctrinal sentiment from Mr. Wesley, and never having formed the idea of a separate association of itinerants and of members, he can scarcely be considered as the head of any party. Mr. Wesley is the father of the Methodists, of whose rise, progress, doctrine, and discipline, we shall now give a very brief account.

Upon Mr. Wesley's return to England, he was invited to preach in several churches, but the concourse of people who followed him was so great, that the churches in general were shut against him. His converts now began to form themselves into a little society, as he and his companions had formerly done at Oxford. They then agreed that they would meet together once a week, "to confess their faults one to another, and pray one for another; that the persons so meeting should be divided into several *bands*, or little companies, none of them of fewer than *five*, or more than *ten* persons; that every one in order should speak as freely, plainly, and concisely as he could, the real state of his heart, with his several temptations and deliverances since their last meeting;—that all the bands should have a conference at eight every Wendesday evening, begun and ended with singing and prayer;—that any who desired to be admitted into this society should be asked, What are your reasons for desiring this? Will you be entirely open, using no kind of reserve? Have you any objection to any of our orders? That after two month's trial, they should be admitted into the society;—that every fourth Saturday should be observed as a day of general intercession;—that on the Sunday se'ennight following, there should be a general *love feast* from seven till ten in the evening;—that no member should be allowed to act in any thing contrary to any order of the society; and that if any persons, after being thrice admonished, should not conform thereto, they should no longer be esteemed as members. Here we have the platform of the system of Methodism. It was still Mr. Wesley's desire and design to preach in the established church, and it is remarkable that he always considered himself a member of it. His plan seems to have been to promote a reformation in the church, instead of separating from it. The rules he observed himself and recommended to his followers seem to have been designed as supplementary to the accustomed ceremonial. He is, without seeming to have intended it, the founder of the most numerous and remarkable religious sect of which we have any account in ancient or modern times.

It must be acknowledged, however, that the doctrine Mr. Wesley taught is not strictly according to the thirty-nine articles.

The Methodists are professed Arminians. They deny the doctrines of *election*, and the certainty of the saints' perseverance.

In regard to original sin, and the extent of human inability, it is not so easy to say what are their precise opinions. They seem to hold, that the effect of the mediation of Christ in regard to all men is, that they may, by the use of the means put in their power, secure their salvation. They certainly go very far in asserting the attainableness of *perfection* in this life. They ground their doctrine on this subject upon such texts as these: "Be perfect." "Herein is our love made perfect, that we may have boldness in the day of judgment, because as he is, so are we in this world."* It is proper farther to notice, that while they deny, as above mentioned, the doctrine of *election* as taught by the Calvinists, they hold that *certain* persons and churches have been elected, and that *great* events are fore-ordained. It is affirmed by respectable authority, that when Mr. Wesley preached in Scotland, he was more cautious in expressing his sentiments on this subject, knowing the Calvinistic creed of the Scottish people. Whatever may be in this, it is certain that his modern followers have not always been so accommodating. Of late years many of their most eminent preachers have brought forward their opi-

* It is a question put by their class leaders, "Have you power over all sin?"

nions on these points with much zeal, and even in a controversial form. Certain it is, however, that the Methodists never have made much progress in North Britain, owing to the hold which the doctrine of the Westminster Confession has upon the minds of the Scotch people, and, it is but fair to add, owing to the residence of the clergy, and the decorous character of the people in general, which may be supposed to make them less accessible to the impressions of terror, one of the chief of the means by which the Methodists aim at operating upon the minds of men. It may also be added, that the minute inspection which the laws of Methodism authorize, as to the very feelings and private exercises of each individual, does not accord with the taciturn, prudent, and independent genius of our people; and perhaps the levy of one shilling quarterly, for the renewal of tickets to constitute full membership, may operate in part as an obstruction. Of late, it became a matter of conference whether Scotland should be relinquished, as bearing heavy on the funds of the society, or whether greater exertions should be made. The latter alternative was adopted; and by employing some of their most eloquent preachers, by erecting better places of worship in more prominent situations, and their usual attention to the cultivation of vocal music, they may perhaps gain their object, unless similar means are employed by the Presbyterians, and more accommodation provided in our large towns for the increasing population. When we look to England and Wales, and the New-World, we see the triumphs of the Methodists. Their numbers are very great, and every year increasing. By the account of the 76th annual conference, held at Bristol in July 1819, it appears that no fewer than 6905 have been added to their society during the past year; that in Great Britain they have 318 stations, each employing at the least two preachers, and in chief towns three or four; in France, they have four missionary stations; in Gibraltar, one; in Brussels, one; in Ceylon and continental India, upwards of twenty missionaries; in Africa six, and more requested; in the West Indies, upwards of forty; in the British provincess of North America, (where the Church of Scotland has done so little,) the Methodists have forty-five preachers.

For their zealous exertions in the conversion of the negroes in the West Indies, in which Dr. Coke, lately deceased, laboured so indefatigably, the Methodists deserve well of the Christain world. Indeed, had it not been for them, our countrymen in these islands would have had scarcely any opportunities of Christian instruction and public worship. As yet they are the chief labourers in British America.

There have been, from time to time, partial separations from the methodists, concerning the administration of the sacraments, service in church hours, &c. but the most formidable divisions have been those relative to the nature and exercise of religious liberty, and to the forms of church government. Disputes on these subjects have produced the *Methodist New Itinerancy*, and the Society of *Revival Methodists*. At the head of the former was Mr Alexander Kilham, who published a book, entitled *the Progress of Liberty among the People called Methodists*, in which he exposed the alleged defects of the "Old Plan," and proposed a form of church government on a broad and liberal basis. He argued, that the whole power of church government was engrossed by the preachers, and that the people were not represented in the meetings of conference, in other words, their *General Assembly*. We cannot pronounce on the merits of the question. When the conference assembled, Mr. Kilham was *unanimously* expelled the connection. The minutes of the trial were published, and every preacher signed his name to a paper, testifying his approbation of the sentence. A declaration of allegiance to the conference (held at Leeds, July 31, 1797,) was drawn up, which was signed by all the preachers present, excepting Messrs. Thom and Eversfield; a third, Mr. Cummin, signified his dissent by letter, "They (says Mr. Myles, in his *History of the Methodists*,) joined Alexander Kilham, and made a schism, under the name of *the New Itinerancy*." The division thus originating amounted to about five thousand. In the year 1806 they had nineteen circuits, thirty travelling or circuit preachers, and about sixty local preachers. They purchased a large and elegant meeting house, called Gibraltar Chapel, in Church Street, where there is an extensive burial ground. The Revival Methodists form a numerous body of the Wesleyan Christians. They are not, however, all of them formally separated from the old connection, though they have, in many towns, separate places for religious worship. In Manchester, Liverpool, Leeds, Stockport, Preston, and Macclesfield, they are numerous. In the latter place they have lately built a neat chapel, having been long separated from the old connection. They have published their rules in a small pamphlet, entitled "*General Rules of a Society of Christian Revivalists at Macclesfield*, with a preface, containing a declaration of doctrines." They are distinguished chiefly, by their claiming as a Christain privilege a right to indulge their feelings as to prayer and praise at all times, and on all occasions,—for example, while the minister is engaged in preaching. No idea can be formed of their number, as they are diffused, more or less, among the general body of methodists.

We are unwilling to pronounce upon the comparative value of Methodism, and the evils which have more or less accompanied it. The enemies of the Methodists say, they have contributed to fill the asylums of lunacy; whereas it is beyond question, that they have in a thousand instances been the means of reclaiming the most vicious and depraved characters. They have been regarded as the most formidable enemies of the establishment; but they have done much good among many who might never have sought more connection with the church, than to procure baptism, marriage, and burial. It is certain they are, generally speaking, good members of society, and very peaceable subjects. They are in general temperate, both in food and dress. They avoid all places of public amusement. They are very kind and sympathizing to their poor and distressed members. *They make a business of religion* more than the generality of Christain professors. Impartiality requires that we just hint at the defects and errors prevalent among them. If we judge from the Monthly Magazine, edited by one of their most respectable members, it is undeniable that too many of their members are guided in their determinations by feelings and impressions: that they are too apt to magnify common events as bordering on the miraculous: that their fixing always the day, and even the moment of conversion, endangers presumption on the one hand, or distracting fears on the other; that their regular detail of each individual's experiences and inward conflicts, seems neither rational nor scriptural, and leads to many errors; and that the practice of lay preaching is apt to expose the work of the Evangelist to contempt. Moreover, their system of itinerancy, and circulation of preachers, which is one of the most striking features of their whole plan, seems not to accord with the Scriptural descriptions of the relation between pastor and flock, and encourages a superficial religion, instead of Christain edification. But what Mr. Wesley said of himself, may be regarded as applicable to most of the preachers of his connexion—"I know, were I myself to preach one whole year in one place, I should preach both myself and most of my congregation asleep."—"We have found, by long and constant experience, that a frequent change of teachers is best." Upon the whole, Methodism seems better calculated to rouse the careless, than to build up believers:—to stimulate the zeal of the Christian world, than to form or regulate churches:—to excite men to seek spiritual food, rather than regularly to administer it. Let Methodists learn from the pious members of the establishments, more regard to order, and to sober mindedness; but let all the churches learn from *them*, more fervour in devotion, more blamelessness of conduct, more brotherly affection, and a conversation which becomes the Gospel. Wesley's *life by Coke and Moore.* Myles' *History of the Methodists. Christian Observer*, vol viii. *Arminian Magazine. Quarterly Review.* Wesley and Coke's *Journals.* Fletcher of Madeley's works, entitled *Checks to Antinomianism, &c.*

MEURTHE, the name of one of the departments in the north-east region of France, and one of the richest in the kingdom. It is bounded on the north by the department of the Moselle, on the west by the *Netherlands*, on the south by that of the Vosges, and on the east by that of the Lower Rhine. It is watered by the Meurthe, (from which it derives its name,) which runs into the Moselle below Frouard, and also by the Seille, the Sarre, and the Vezouze, which flows into the Meurthe at Luneville. Its principal productions are, corn, wines, tobacco, hemp, madder, saffron, wood of construction, iron mines, and salt springs. In the arrondissement of Luneville there are several glass-works, particularly those of St. Quirin. Phalsbourg, in the arrondissement of Sarrebourg, is celebrated for its liqueurs. Chateau-Salins derives its name from the salt-springs which prevail there. Dieuze, in the same canton, has likewise salt-springs. In the middle of a marsh in the neighbourhood of Nanci, an obelisk marks the place where Charles the Bold perished. In the neighbourhood of Toul, earthen ware is manufactured. The following are the principal towns, with their population.

Nanci (the capital)	29,740
Luneville	9,797
Toul	6,949
Chateau-Salins	2,110
Sarrebourg	1,454

Luneville, situated between the Vezouze and the Meurthe, is celebrated for the treaty signed at it in 1801, between France and Austria. It has an academy and a good library.

The department contains 6430 square kilometres, or 325 square leagues. The forests amount to about 227 sectores, or 445 thousand acres, of which nearly 100 thousand belong to the government, 65 thousand to the communes, and the remainder to individuals. The contributions in the year 1801 amounted to 2,681,581 francs. Population 342,107.

MEXICO.

Mexico, (town of,) the capital city of New Spain, is situated in 19°, 25', 45" of north latitude, and 99°, 5', 15" of west longitude, 7470 feet above the level of the sea. Its name imports, in the Aztec language, the habitation of the god of war; but, before the year 1530, it was more commonly called Tenochtitlan, which Cortez corrupted into Temixtitan. Its situation on an isthmus, washed by the South Sea and the Atlantic Ocean, is peculiarly favourable for commercial communications; but the state of the coast, and the want of ports on the Atlantic, oppose great obstacles to its prosperity. It stands in the midst of a fine valley, about 70 leagues in circumference, and was formerly surrounded by a salt-water lake, and intersected by navigable canals. It was accessible by means of three dikes, or causeways, about 20 feet in breadth, which were carried through the lake, for the space of more than a league, in different directions. But the water of the lake, which seems to have begun to decrease long before the arrival of the Spaniards, is above two miles distant from the city in its present state. The city was almost completely destroyed at its conquest by Cortez, by whom it was rebuilt on the same spot, so that the present streets have for the most part the same direction as the old ones, running nearly from north to south, and from east to west, forming a great square, of which each side is nearly 9021 feet in extent. In its ancient state, surrounded with water, and founded on islands covered with verdure, the capital of Mexico must have resembled some of the cities of China or of Holland. It is still one of the finest cities ever built by Europeans, and is surpassed by few towns, even on the old continent, for the uniform level of the ground on which it stands, the regularity and breadth of the streets, and the extent of the public places. The houses, built of hewn stone, (which is a porous amygdaloid, or a porphyry of vitreous feld-spath,) have a great appearance of solidity and magnificence. They are not loaded with ornaments, and have none of those wooden balconies and galleries which so much disfigure the European houses in both the Indies. The balustrades and gates are all of Biscay-iron, ornamented with bronze; and, instead of roofs, there are terraces resembling those of Italy and other southern countries. The architecture in general is of a very pure style; and there are several edifices of a very beautiful structure. Those which usually attract the attention of a stranger, are the *cathedral*, a small part of which is in the Gothic style, and the principal edifice, which is of recent date and fine proportion, has two towers, ornamented with pilasters and statues; the *treasury*, adjoining to the palace of the viceroys; the *convents*, particularly that of St. Francis; the *hospital*, which maintains 1400 children and old people; the *acordada*, a fine edifice provided with spacious and well aired-prisons, capable of containing more than 1200 individuals; the *school of mines*, a beautiful new building, which contains fine collections in physics, mechanics, and mineralogy; the *botanical garden*, small, but rich in the more rare and interesting vegetable productions; the *university public library*; the *academy of fine arts*; the *equestrian statue* of Charles IV. in the Plaza Mayor; and the *sepulchral monument* to Cortez, in a chapel of the Hospital de los Naturales. The town has been much embellished since the year 1769. Two great palaces or hotels have been recently constructed by Mexican artists from the academy of the arts in fine captial, one of which, in the interior of the court, exhibits a very beautiful oval peristyle of coupled columns. But it is the extent and uniform regularity of the city, and the breadth and straightness of the streets, more than the grandeur or number of its monuments, which excite admiration; while the excellence of the police preserves every thing in proper order and repair. Most of the streets have very broad pavements, and are both clean and well lighted. The supply of water is well regulated; and, as that which is found by digging is of a brackish quality, spring water is conveyed from a considerable distance by means of two aqueducts of modern construction, which are well worthy of notice. One of them, leading from the insulated hill of Chapoltepec, is carried upon arches for the space of 10,826 feet, and the other from the Cordillera, which separates the valley of Mexico from that of Lerma and Toluca, is about 33,464 feet in length, but, on account of the declivity of the ground, is conducted over arches for no more than a third part of the space. The ancient dikes, or causeways, still exist; and others have been formed across the marshy grounds, which at once serve the purposes of roads for carriages, and of mounds to resist the overflowings of the lake. There are few remains of Mexican antiquities to be found in the capital. The ancient temples, or teocallis, which were truncated pyramids, with a broad base, and frequently 150 feet in height, covered with wooden cupolas and altars, were so much used during the siege as places of defence, that most of them were destroyed in its progress, and the rest afterwards thrown down, partly as being heathen monuments displeasing to Popish bigotry, and partly as furnishing strong-holds to the Indian insurgents. The few remaining relics of Mexican art are the dikes and aqueducts; the stone of the sacrifice; the great calendar monument; the colossal statue of the goddess Teoyaomiqui, which lies covered with a few inches of earth in one of the galleries of the university; the Aztec manuscripts, or hieroglyphical pictures, painted on agaue paper, stagskins, and cotton cloth, which are preserved rather carelessly in one of the archives of the viceroy's palace; the foundations of the palace of the kings of Alcolhuacan at Tezcuco; the colossal relievo, traced on the porphyritical rock called Penol de los Banos; with several other objects, which are considered as resembling the works of the ancient Mongol race.

The population of Mexico, according to the most recent and certain data, amounts to not less than 135,000, or 140,000, including the military, who are seldom fewer than 5000 or 6000. According to M. Humboldt, the whole may be classed under the following heads—

White Europeans . . .	2 500
White Creoles	65,000
Indigenous, (copper coloured) .	33 000
Mestizoes, mixture of Whites and Indians	26,000
Mulattoes	10,000
	136,500

There are 23 male convents, containing about 1200 individuals, of whom 580 are priests and choristers; and 15 female convents, containing 2100 individuals, of whom nearly 900 are professed religieuses. The market of Mexico is abundantly supplied with provisions, particularly with roots and fruits of every description; which may be seen every morning at sunrise brought down the canals in boats by the Indians, along with a great quantity of flowers. The greater part of these roots are cultivated on the chinampas, or floating gardens, in the adjoining lakes. These gardens are known to have been in use as far back as the end of the 14th century, and are supposed to have been suggested by the natural occurrence of small portions of earth covered with herbs, and bound together by their roots, detached from the banks, and floating on the surface of the water, or sometimes uniting together so as to form small islands. They were afterward artificially constructed, by making rafts of reeds, rushes, roots, and brushwood, covering these with black mould, naturally impregnated with muriate of soda, but gradually purified from the salt, and rendered fertile by washing it with the water of the lake. Some of these gardens are moveable, and driven about by the winds; but others are anchored, or attached to the shore, and are towed, or pushed with poles from one spot to another. Frequently a cottage is built upon them for the residence of an Indian, who acts as keeper or guard for a whole group. They are usually 328 feet in length, by 16 or 19 in breadth, rising about 3 feet above the surrounding water; but many of them have now become fixed, lying along the canal, and separated from each other by narrow ditches. The edges of these squares, formed in this manner, are generally ornamented with flowers, and sometimes with a hedge of rose-bushes. On a soil thus constantly refreshed with water, the vegetation is extremely vigorous; and a great variety of vegetables, particularly beans, peas, pimento, potatoes, artichokes, and cauliflowers are raised upon them.

The town of Mexico is scarcely less endangered by inundations than that of Lima by earthquakes; and in every 20 years, at least, has been greatly injured by the overflowing waters of the neighbouring lakes. All these lakes, except that of Tezcuco, are on a higher level than the city; and even the bed of this nearest lake is progressively rising by the accumulation of mud, while the paved streets of Mexico remain a fixed plane. These inundations occasioned less inconvenience in the old city, when the inhabitants were accustomed to live much in their canoes, and when the houses were so constructed, that boats could pass through the lower story. But the losses experienced in the modern city were much greater, and more alarming to the inhabitants, who have been obliged to abandon the old Indian system of dikes or mounds, which were found insufficient to repel the floods, and have adopted the plan of canals of evacuation to carry off the superabundant waters. At one period, in consequence of these works being interrupted, Mexico remained inundated for five years, from 1629 to 1634. The greatest wretchedness prevailed among the lower orders; all commerce was at a stand; and it was only by frequent earthquakes opening the ground of the valley that the waters were removed. At length, after various schemes and delays, an immense outlet through the mountains to the north-east was completed in 1789, called the Desague de Hue-buetoca, which is one of the most gigantic hydraulic operations ever executed by man, and which, if filled with water to the depth of 32 feet, would allow the largest ships of war to pass. The canal is more than four leagues and a half in length; and a fourth part of the whole is cut through the hills of Nochistongo. For the space of 11.482 feet, the depth of the cut is from 98 to 131 feet; and at the highest part of the ridge, for the space of 2624 feet, the perpendicular depth is not less than from 147 to 196 feet, while the breadth at the top is from 278 to 360 feet. But, in spite of all the means which have been used to secure the capital against inundation from the north and north-west, it is still exposed to great risks from the adjoining lake of Tezcuco, for the draining of which a canal is begun to be executed, which will extend above 104,660 feet, and cost £125.000. These operations have proved fatal to multitudes of Indians, who are compelled to labour in the public works to the neglect of their own domestic affairs; and who, besides perishing in great numbers from disease and casualties, are reduced to a general state of poverty.

The environs of Mexico present a rich and varied appearance, when viewed in the morning from the towers of the cathedral, or the hill of Chapoltepec. The eye, (says M. Humboldt,) sweeps over a vast plain of carefully cultivated fields, which extend to the very feet of the colossal mountains covered with perpetual snow. The city appears as if washed by the waters of the lake Tezcuco, whose basin, surrounded with villages and hamlets, brings to mind the most beautiful lakes of the mountains of Swisserland. Large avenues of elms and poplars lead in every direction to the capital; and two aqueducts, constructed over arches of very great elevation, cross the plain, and exhibit an appearance equally agreeable and interesting. The magnificent convent of Neustra Sonora de Guadalupe appears joined to the mountains of Tapeyacac, among ravines, which shelter a few dates and young yucca trees. Towards the south, the whole track between San Angel Tacabaya, and San Augusta de las Cuevas, appears an immense garden of orange, peach, apple, cherry, and other European fruit-trees. This beautiful cultivation forms a singular contrast with the wild appearance of the naked mountains, which inclose the valley, among which the famous volcanos of Puebla Popocatepetl, and Iztaccicihuatl are the most distinguished. The first of these forms an enormous cone, of which the crater, continually inflamed and throwing up smoke and ashes, opens in the midst of eternal snows." See Robertson's *History of America*, and Humboldt's *Essay on New Spain*. (*q*)

MEXICO, or New Spain, is one of the nine great governments into which the Spanish possessions in America are divided; and is by far the most important of them all, both on account of its territorial wealth and its favourable position for commercial communications. Its Indian name, Mexico, signifies, in the Aztec language, the habitation of the god of war; and the designation of New Spain, first applied in 1518 to the province of Yucatan, and afterwards to the whole empire of Montezuma, now includes all the extent of country over which the viceroy of Mexico exercises his authority, lying between the 10th and 38th degrees of north latitude: but the kingdom or captain-generalship of Guatimala, is considered a distinct government, and is generally excluded from the proper territories of Mexico. In this more limited view, then, the kingdom of New Spain extends from the 16th to the 38th degree of north latitude, about 610 leagues in length, and 364 at its greatest breadth. One half of its whole surface is situated under the burning sky of the tropics, and the other under the temperate zone: but, from the singular elevation of the ground above the level of the sea, nearly three-fifths of the country under the torrid zone enjoy a temperate instead of a sultry climate. The whole interior of the viceroyalty of Mexico forms one immense plain, elevated from 6560 to 8200 feet above the level of the neighbouring seas, extending from the 18th to the 40th degree of north latitude. The descent from this central table land towards Acapulco, on the west coast, is a regular progress from a cold to a hot climate, by a road which may be made fit for carriages: while, on the east coast to Vera Cruz, the descent is short and rapid, passable only by mules, but likely to be soon rendered accessible for carriages, by the construction of a superb causeway, which was begun about the commencement of the present century. From Mexico to New Biscay, the plain preserves an equal elevation, and lies under a climate rather cold than temperate; and it is only the coasts of this vast kingdom which possess a warm climate, adapted for the productions of the West Indies. The mean temperature of these plains, which are situated within the tropics, and not more than 984 feet above the level of the sea, and which are called by the natives Terras Calientes, is about 77° of Fahrenheit. On the eastern coast, the great heats are occasionally interrupted by strata of cold air brought by the winds from Hudson's Bay, from October to March, and which frequently cool the atmosphere to such a degree, that the thermometer of Fahrenheit stands at 60° at Vera Cruz; but, on the western coast, in the town and neighbourhood of Acapulco, the climate is the hottest and most unhealthy in the world. On the declivity of the Cordillera, at the elevation of 3930 to 4920 feet, there prevails perpetually a soft spring temperature, seldom varying more than seven or nine degrees, and where the extremes of heat and cold are equally unknown. This region is called the Tierras Templadas, in which the mean temperature of the whole year is from 68° to 70° of Fahrenheit; but the clouds, which ascend above the lower plains, usually settle on this height, and occasion frequent thick fogs. The third zone, called Terras Frias, comprehends the plains which are elevated more than 7200 feet, and of which the mean temperature is under 62°. In the plains which are still more elevated, even to the height of 8200 feet, the climate, even within the tropics, is rude and chill, the heat during a great part of the day never rising to more than 51° or 55°. The winters here are not indeed extremely boisterous; but the sun, even in summer, has not sufficient power in the rarefied atmosphere to accelerate vegetation and bring fruits to maturity. In general, the equinoctial regions of New Spain resemble the temperate zones in soil and climate, and vegetation; but, in the central table land, the temperature is extremely cold in winter. The region of perpetual snow in the 19th and 20th degrees of latitude, commences at about 15,000 feet of elevation; and, in the month of January, descends to about 12,000; but there are occasional falls of snow between the parallels of 18 and 22 at the height of 9840 feet, and even the towns of Mexico and Valladolid, which are more than 200 and 300 feet lower. From the 22° to the 30° of north latitude, the rains fall only in the months of June, July, August, and September; but, even then, are not frequent in the interior of the country. The declivities of the Cordillera are exposed to humid winds and frequent fogs; and the sea coasts receive immense quantities of rain from the month of June to September. With the exception of a few sea ports and deep vallies, where intermittent fevers prevail, the climate of New Spain may be accounted remarkably salubrious.

On each coast, the low grounds are intersected by very inconsiderable hills: but, in the central plain, between the town of Mexico and the city of Cordova, there are groupes of lofty mountains, equal in height to any in the new continent, particularly those of Popocatepetl, *i. e.* the smoke mountain, Iztaccihuatl, *i. e.* the white woman, Citlaltepetl, *i. e.* star mountain or the Pic d'Ouzaba, and Nauhcampatepetl, *i. e.* square mountain, or the Cofre de Perote, which are respectively 17,716, 15,700, 17,371, and 13,414 feet above the level of the sea. To the north of latitude 19° the Cordillera takes the name of Sierra Madre, and runs to the north-west. Beyond the city of Guanaxuato, in latitude 21°, it becomes of an extraordinary breadth, and divides into three branches. Of these the most eastern runs in the direction of Charcas, and loses itself in the new kingdom of Leon. The western branch, occupying part of the intendancy of Guadalaxara, sinks rapidly after psssing Bolanos, and stretches to the banks of the Rio Gila, but acquires again a considerable height under the 30th parallel, near the Gulf of California, when it forms the mountains de la Pimeria Alta, celebrated for the gold washed down from their sides. The third branch, which may be considered as the central chain of the Mexican Andes, occupies the whole extent of the intendancy of Zacatecas, and may be traced to the Sierra de los Mimbres, west of the Rio Grande del Norte, thence traversing New Mexico, and joining the Crane mountains and Sierra Verde. This central branch is the crest which divides the waters between the Pacific and Atlantic oceans; and it was a continuation of this branch which Fidler and Mackenzie examined under the 50° and 55° of north latitude.

There are five burning volcanos in Mexico, namely, Ouzaba, Popocatepetl, Tustla, Jorullo, and Colinia; but earthquakes and eruptions are not frequent. The former are chiefly experienced on the coast of the Pacific, and in the environs of the capital, but never produce such desolating effects as in the provinces of Guatimala, Cumana, Quito, and Lima.

In New Spain there is a great want of water, and of navigable rivers. The great river of the north (Rio Bravo del Norte) and the Rio Colorado, are the only rivers distingushed by the length of their course, and their volume of water. The first of these runs through a course of 512 leagues from its source in the mountains of Sierra Verde, east from the lake of Timpanogos, to its mouth in the province of New Santander in the Gulf of Mexico; and the latter flows 250 leagues from its origin in a hilly tract, about 13 leagues west from that of the del Norte, till it falls into the Gulf of California. This last mentioned river is formed by the union of the Zauganames and the Nabajoa; and itself forms a junction with the Gila about the 32d parallel of north latitude. In the southern part of Mexico, the narrow form of the continent prevents the collection of a great mass of water, and the rapid declivity of the Cordillera abounds in torrents rather than rivers. Those which are most adapted for navigation are, the Guasacualco and the Alvarado to the south-east of Vera Cruz; the Moctezuma, which carries the waters of lake Tenochtitlan to the Panuco; the Zacatula, at a small sea-port of the Pacific Ocean on the frontiers dividing the intendancies of Mexico and Valladolid; and the great river of Santiago, formed by the junction of the Lerma and Laxas, and falling into the South Sea at the port of San Blas.

The lakes, with which Mexico abounds, are considered as merely the remains of immense basins of water, which appear to have formerly existed on the high plains of the Cordillera, and are said to be annually diminishing. The most remarkable are the great lake of Chapala in New Gallicia, nearly 160 leagues square; the lakes in the valley of Mexico, which cover a fourth part of the district; the lake of Patzcuaro in the intendancy of Valladolid, which is accounted one of the most picturesque situations in the world; the lakes of Mextitlan and Parras in New Biscay; and the great lake of Nicaragua, about 200 miles in circumference, in the kingdom of Guatimala.

The mineral productions of this country form one of the principal sources of its wealth, and are found in a great variety of rocks and forms throughout the range of the Cordilleras; but the districts of Guanaxuato, Zacatecas, and Catorce are the most abundant, and supply more than one half of the whole amount of precious metals exported from the country. The former alone yields one-fourth of the silver of Mexico, and one-sixth of the produce of all America. The richest mines of New Spain, arranged according to the quantity of metal which they yield, are

Guanaxuato, in the intendancy of the same name.
Catorce, in the intendancy of San Louis Potosi.
Zacatecas, in the intendancy of the same name.
Real del Monte, in the intendancy of Mexico.
Bolanos, in the intendancy of Guadalaxara.
Guarisamey, in the intendancy of Durango.
Sombrerete, in the intendancy of Zacatecas.
Tasco, in the intendancy of Mexico.
Batopilas, in the intendancy of Durango.
Zimapan, in the intendancy of Mexico.
Fremillo, in the intendancy of Zacatecas.
Ramos, in the intendancy of San Louis Potosi; and
Parral, in the intendancy of Durango.

The Mexican mines are considered as forming eight groupes, &c. and are almost all placed either on the ridge or the western slope of the Cordillera of Anahuac; and it is a remarkable circumstance, that the tract which yields the greatest quantity of silver, between 21 and 24½ degrees of latitude, corresponds, in distance from the equator, with the district of greatest metallic wealth in Peru. The mean annual produce of the whole is 2,500,000 marcs of silver, about ten times more than what is furnished by all the mines of Europe; and 700 marcs of gold, about an equal quantity to what the European mines afford. Yet the ore is by no means remarkably rich; and the mean produce of the whole vein of Guanaxuato is four ounces of silver per quintal of minerals. The mining operations also are carried on at great expense, and not always in the most economical manner. In the mine of Valenciana, one of the richest in Guanaxuato, there is an administrator with a salary of 2500*l.* sterling; an overseer under him, with several under-overseers, and nine master miners, with 1800 workmen labouring in the interior of the mine. The expense of the powder alone has often amounted to 16,668*l.*, and of the steel for implements to 6250*l.* A new draught pit, 87 feet in circumference, and which was to reach to the enormous perpendicular depth of 1685 feet, was advanced, (when seen by M. Humboldt, in 1803,) to the depth of 603 feet, and was estimated to cost a million of piastres, and to require the labour of twelve years before it could be completed. The American miners have learned little from those of Europe since the 16th century, except the blowing with powder; and, though the court of Madrid has frequently attempted to introduce into the colonies the use of the more recent improvements in mechanical and chemical science, yet, as the mines are considered as the property of individuals, the government has no influence in directing the operations.

In the beginning of the 18th century, the quantity of gold and silver coined at Mexico, (which generally coincides with the quantity produced by the mines) was only from five to six millions annually; but the amount has been constantly on the increase for the space of 113 years, excepting the period from 1760 to 1767, so as to have been tripled in 50, and sextupled in 100 years. This enormous increase observable in late years, is attributed by M. Humboldt to a number of concurring causes, particularly to "the increase of population on the table land of Mexico, the progress of knowledge and national industry, the freedom of trade conceded to America in 1778, the facility of procuring at a cheaper rate the iron and steel necessary for the mines, the fall in the price of mercury, the discovery of the mines of Catorce and Valentiana, and the establishment of the Tribunal de Mineria." This progress of the mining operations is exhibited by the following Table of the gold and silver given into the mint of Mexico in periods of ten years.

Periods.				Value in piastres.
From	1690	to	1699	43,871,335
	1700		1709	51,731,034
	1710		1719	65,747,027
	1720		1729	84,153,223
	1730		1739	90,529,730
	1740		1749	111,855,040
	1750		1759	125,750,094
	1760		1769	112,828,860
	1770		1779	165,181,729
	1780		1789	93,504,554
	1790		1799	231,080,214
Total from	1690	to	1799	1,276.232 840

The other metals in New Spain have been greatly neglected, but are sufficiently worthy of attention; *copper* is found in a native state, and under the form of vitreous and oxidulated copper in several mines; and, from the quantity of instruments of that metal found among the ancient Mexicans, must be plentiful in the country. About 1565 quintals of plate copper, and 13,947 lbs. of wrought copper, amounting altogether to the value of 42,131 piastres, were exported from Mexico in 1802. *Tin* is found in veins, but is extracted chiefly from the earth of alluvial lands brought down the ravines; and about 58½ quintals were exported in 1803, to the value of 1,483 piastres. *Iron*, though little used by the ancient Mexicans, is more abundant than is generally believed, and particularly in the *provincias internas;* but is wrought with any degree of spirit only when a maritime war has interrupted the importation of steel and iron from Europe. *Lead* is very abundant in various parts of New Spain, but the mines are not wrought to any extent; and only 330 quintals were exported in 1802, besides what is required in the country. *Mercury* might be procured in considerable quantities from the numerous veins of Cinnebar which are found in Mexico; and, instead of being received, may one day be supplied by America; but at present 16,000 quintals are annually imported for the mining operations of New Spain. *Zinc*, *antimony*, and *arsenic* are found in several places, but *cobalt* has not been discovered among the minerals of the country; and *manganese* is less abundant than in the corresponding latitudes of the old continent.

Coal also is very rare, and is most abundant to the west of Sierra Verde near the lake of Timpanogos. *Rock salt* is found in the same place; and *soda* is merely disseminated in the argillaceous lands, which cover the ridge of the Cordilleras. The most abundant salt mine in Mexico is the lake of Penon Blaoco, in the intendancy of San Luis Potosi, the bottom of which is a bed of argil, yielding 12 or 13 per cent. of muriate of soda; but, as the Indians, who form the great part of the population, continue to season their food with pimento instead of salt, the consumption of these articles in Mexico is chiefly confined to the amalgamation of silver minerals, for which purpose from 20 to 30 fanegos are annually imported from Europe.

All the metallic wealth of New Spain, as well as in the other colonies, is in the hands of individuals; and the government is not even proprietor of the great levels. Individuals receive from the king a grant of a certain number of measures in the direction of a vein or bed; and are bound in return to pay very moderate duties on the minerals extracted from the mines, amounting in general to about 13 per cent. The number of persons employed in these subterraneous operations, throughout the whole of New Spain, does not exceed 30,000, which is only about $\frac{1}{200}$ of the whole population. The labour of a miner is entirely free; and no Indian or Mestizoe can be compelled to engage in the working of mines, or to continue in one place when he is thus employed. No miners are better paid than those of Mexico; and no where do they enjoy in greater security the fruit of their labours. Nor is their occupation observed to be more destructive of health than that of the other classes, although their exertions are great, and the temperature in which they exist very high. In several of the mines the heat is eleven degrees of Fahrenheit above the mean temperatures of Jamaica and Pondicherry; and the labourers, who carry the minerals on their backs, are exposed to a change of temperature, in ascending and descending, of more than

40 degrees. Yet, in these circumstances, they will remain for six hours under a load of 225 or 350 pounds, ascending eight or ten times successively stairs of 1800 steps. But this labour is accounted unhealthy, if they enter the mines above three days in the week. Those who blow the rock with powder, are found to suffer most in their health; and hence they seldom continue more than five or six years at this employment. They are well paid in every department of the work; and generally gain from 20 to 24 shillings per week, while labourers in the open air can earn only from six shillings and three-pence to seven shillings and sixpence in the same space of time. They are, nevertheless, much addicted to pilfering; and, though almost naked, contrive a number of plans to secrete the richer minerals, concealing them in their hair, their mouths, under their arm-pits, and sometimes even inserting them by means of cylinders of clay into their anus. They are of consequence regularly searched upon leaving the pit; and a register kept of the minerals detected about their persons, which, in one valuable mine, has been known to amount nearly to 3000*l.* per annum.

In this mountainous and extensive country, whose geometrical position and geological configuration contribute in producing the greatest diversity of climate, the variety of indigenous productions is immense; and scarcely a plant exists in the rest of the globe, which is not capable of being cultivated in some part of New Spain. Much has been done by distinguished botanists, employed by the government, to examine the vegetable riches of the country; but still many tracts remain to be explored, and new plants are daily discovered even in the central table-land, and in the very vicinity of the capital. The mines are by no means the principal sources of Mexican wealth; neither have they proved in general such obstructions, as has been imagined, to the progress of agriculture, which has been gradually ameliorating since the end of the 17th century. On the contrary, they have contributed powerfully, in many cases, to promote the cultivation of the soil. The subsistence required for the labourers and cattle employed in mining operations, has occasioned the establishment of farms in their neighbourhood, and brought under culture every spot of earth in the adjoining declivities and ravines. Nor do the natives easily forsake these settlements after the subterraneous operations have ceased, but continue rather to prefer these retired situations, and preserve a strong attachment to the residence of their forefathers.

The vegetable productions, which constitute the chief support of the Mexican people, form the great object of their agriculture. Among these the *banana* is one of the most important, corresponding in utility with the grain of Europe, and the rice of Asia; and scarcely any other plant is capable of producing so great a mass of nutritive substance on the same space of ground. The fruit is ready for being gathered in the tenth or eleventh month after the suckers are planted; and the plantation is perpetuated by fresh shoots, without any other trouble than merely cutting the stalks on which the fruit is ripe, and digging slightly around the roots once or twice a-year. A spot of 1076 square feet, containing from 30 to 40 plants, yields about 4414 pounds avoirdupoise of nutritive food, while the same space in wheat is calculated to yield only 30 lbs. and in potatoes not more than 90 lbs.; so that the produce of bananas is to the former as 133 to 1, and to the latter as 44 to 1. In fertile regions, a legal arpent, (about 54,998 square feet,) planted with the large banana, will maintain 50 individuals; while the same extent sown with wheat would furnish subsistence only to two persons. The fruit is prepared in a variety of ways; being dressed like the potatoe, or dried and pounded into flour, or preserved like figs, by exposure to the sun, when it acquires the aspect and odour of smoked ham. In the same region with the banana is cultivated the *juca*, which yields the flour of manioc, the bread of which is known under the name of cassave. This bread is very nutritive, perhaps on account of the sugar which it contains; but, from a deficiency of gluten, it is very brittle, and inconvenient to be carried. The fecula of manioc, however, when grated, dried, and smoked, is unalterable, and is neither attacked by insects nor worms. Even the juice of the bitter root, which, in its natural state, is an active poison, may be converted, by boiling and skimming, into a nutritive brownish soup. The cultivation of the manioc requires more care than that of the banana, resembling rather that of the potatoe, and yielding its crop about seven or eight months after the plantation of the slips. *Maize*, an indigenous American grain, occupies the same region with the two last mentioned, and is of still greater importance than either. Excepting a species of rye and of barley, maize is supposed to have been the only kind of grain known to the Americans before the arrival of the Spaniards, and is capable of being cultivated over a much greater extent of latitude than the cerealia of the old continent. Its fecundity in Mexico is above any thing that Europeans can imagine. When favoured by heat and humidity, the plant acquires a height of from $6\frac{1}{2}$ to $9\frac{1}{2}$ feet, and yields at an average in the equinoxial region of New Spain. 150 grains for one. In fertile lands, one fanega of maize produces from 300 to 400, and, in the beautiful plains between San Juan del Rio and Queretaro, sometimes even 800; but, under the temperate zone, it produces in general only from 70 to 80 for 1, though, sometimes, from 180 to 200.

The maize is the principal food of the Mexicans, and its price modifies that of all other provisions. There is no grain more unequal in its produce, according to the changes of moisture or of temperature, varying in the same field in different years from 40 to 300 for 1; and when the harvest is poor, either from want of rain or from premature frost, the greatest distress is experienced. Its mean price is 5 livres in the interior; but as there are no magazines in the country, to make the superabundance of one year supply the deficiency of another, it has been known to fall as low as $2\frac{1}{2}$ livres, and to rise as high as 25 The natives, in these cases, feed on unripe fruit, berries, and roots, which occasion many diseases and great mortality among the children. Some kinds of maize ripen in six weeks or two months; so that in warm and moist districts, two or three crops are raised in the year. This grain is eaten boiled or roasted, and its meal employed in gruels, or made into bread. By partly malting and infusing the grain of maize, the Indians prepare a great variety of spiritous, acid, and sugary drinks, generally known by the name of *chicka*, some of which resemble beer, and others cider. The juice pressed from the stalk, which contains a considerable quantity of saccharine matter in the tropical region, yields a rough sugar, or may be fermented into a spiritous liquor, called pulque de mahis, which is an important object of commerce in the valley of Toluca. This grain will keep, in the temperate climates, for three years; and, where the mean temperature is below 57° of Fahrenheit, for five or six, provided the crop is not cut too early. The whole of New Spain is calculated to produce at an average 17 millions of fanegas of maize, or 1765½ millions of lbs. avoirdupoise; and, in good years there is more reaped than the country can consume; but, as it almost never succeeds in the warmer and in the colder regions, much of the interior commerce consists in the conveyance of this grain, great quantities of which also are sent to the Spanish islands in the West Indies.

The cerealia of Europe, viz. wheat, spelt, barley, oats, and rye, are no where cultivated in the equinoxial part of Mexico, unless in elevations of 2600 or 2900 feet; and on the declivity of the Cordilleras. between Vera Cruz and Acapulco, these grains are not sown under an elevation of 3900 or 4200 feet; but it appears that wheat will ripen in much smaller elevations, even of 1600 or 1900, under latitude 10°. These grains, in most parts of New Spain, suffer chiefly from the deficiency of rain, and much use is made of irrigation in their culture. The *wheat* is watered when the young plants begin to spring up in January, and again in the beginning of March, when the ear is becoming visible; sometimes the whole field is inundated before sowing. In the more fertile parts of the table land, such as between Queretaro and the town of Leon, the wheat returns 40, and even 50 or 60 for 1; and the mean produce over Mexico is from 25 to 30 for 1. The whole produce of wheat in New Spain is estimated at 331,000,000 lbs. avoirdupoise, and its mean price is from 17s. to 21s per carga, which weighs 331 lbs. avoirdupoise; but the high price of carriage frequently raises it to 37s. or 43s. The Mexican wheat is of the best quality, large, white, and nutritive; but is with difficulty preserved more than two or three years. *Rye* and *barley* are cultivated in the highest regions; and the latter yields abundant crops in places where the thermometer is seldom above 57° of Fahrenheit. *Oats* are little cultivated, and seldom seen in the country. The *potatoe* appears to have been introduced into Mexico along with the European grains, and to have been brought from Peru or New Grenada. It is cultivated in the highest and coldest regions of the Cordilleras, and grows in some places to the size of nearly one foot in diameter, while the quality is excellent. It is preserved by the natives for whole years by exposing it to the frost, and drying it in the sun. Other nutritive roots are, the *oca*, which grows only in the cold and temperate regions; the *iguame*, a root which, in a fertile soil and warm climate, grows to so enormous a size as to weigh not less than 55 or 60 lbs.; and the *batate*, which also requires a warm country. Among the useful plants of Mexico may also be mentioned the *cacomite*, a species of tigridia, the root of which yields a nutritive flour; the *love-apple*; the *earth-pistachio*; and the different kinds of *pimento*, the fruit of which is as indispensable to the natives as salt to the whites.

The Mexicans possess all the fruit trees and garden stuffs of Europe; but it is not easy to ascertain which of these existed among them before the arrival of the Spaniards. It is certain that they were always acquainted with onions, haricots, gourds, and several varieties of cicer; and Cortez expressly mentions onions, leeks, garlic, cresses, borrage, sorrel, and artichokes; but no species of cabbage or turnip appears to have been cultivated among them. The central table land produces in the greatest abundance, cherries, prunes, peaches, apricots, figs, grapes, melons, apples and pears. The ecclesiastics, and particularly the missionaries, contribute greatly to spread the European fruits and vegetables from one end of the American continent to the other. Even the orange and citron trees are now cultivated throughout all New Spain, nay on the central table land, and there can be little doubt that the olive and mulberry, with hemp and flax, would equally flourish in New Spain, were not their cultivation discouraged by the jealousy of the mother country. Besides extracting liquors from the maize, manioc, banana, and the pulp of different kinds of mimosa, the Mexicans cultivate a species of *agave*, called maguey de pulque, for the express purpose of preparing a spiritous liquor from its juice, which is carefully collected by cutting the central leaves at the period of efflorescence, and of which one plant, about five feet in height, will yield, in the course of five months, a quantity equal to 67 130 cubic inches. Even in an ordinary soil, 150 bottles may be procured from one maguey in the season, and the value of each day's juice is estimated at 10 or 12 sols. The plant multiplies with great facility, and resists the cold of the higher regions; and its cultivation is found to be a sure mode of gain. The juice has a very agreeable sour taste, and so very easily ferments, that in three or four days a viscous beverage resembling cider is procured. It has a fetid odour like putrid meat; but, after custom has surmounted this obstacle to its use, it is generally preferred by Europeans to every other liquor, and is accounted stomachic, strengthening, and nutritive.—There are plantations in the north of Toluca, where the best is produced, which annually bring in more than 1600*l.* sterling; and this cultivation is so profitable to the revenue, that, in 1793, the duties which it paid in the three cities of Mexico, Puebla, and Toluca, amounted to the sum of 178,880*l* sterling. A very intoxicating brandy is procured from a different species of the same plant, which is prohibited by the government as prejudicial to the Spanish brandy trade, but which is manufactured in an illicit manner to a great extent. The leaves of this agaue are also manufactured into thread and paper; and its prickles were formerly employed as pins or nails by the Indians; so that, next to the maize or potatoe, it may be considered as the most useful production in the mountainous districts of equinoxial America. The *vine* is little cultivated, in consequence of government restrictions; but might be raised with great success in all the mountainous and temperate regions.

The cultivation of those productions which supply the raw materials of commerce and manufactures has recently increased in Mexico to a considerable extent. The profit of raising *cotton* is more than double that of grain, and that of *sugar* more than four times; but it is only in the warmer districts that these crops can be cultivated. In these districts there are already plantations cultivated by free Indians, which yield annually about a million and a half pounds of sugar; and in process of time the continent of America is likely to supplant the West India Islands in the cultivation of sugar, coffee, and cotton.

Cotton was one of the ancient objects of cultivation in Mexico, and some of the finest quality is raised on the western coast; but as the inhabitants of these places are still unacquainted with the use of machines for separating the cotton from the seed, the price of carriage is a great obstacle to this branch of Mexican agriculture. *Flax* and *hemp* may be advantageously cultivated, wherever the climate does not admit the growth of cotton; but their culture has hitherto been discouraged. *Coffee* is little used in Mexico; and is only beginning to be cultivated in the country. The *cocoa tree* was generally cultivated before the arrival of the Spaniards, by whom it was conveyed to the Canaries or Philippines, but is now almost totally neglected. Its seeds were formerly used as money, and in some places are still applied to that purpose by the common people, at the rate of six grains for one sol. *Vanilla*, though bearing a high price in Europe, is little cultivated in Mexico, except in the intendancies of Vera Cruz and Oaxaca. It thrives wherever there is heat, shade, and moisture, and is planted so as to climb along the trunks of trees. It principally abounds on the eastern slope of the Cordillera of Anahuac, between the 19° or 20° of latitude, and in the same latitude is procured the *sarsaparilla* and *jalap* (or purga de Xalapa,) of which last between two and three thousand quintals are annually exported from Vera Cruz. *Tobacco*, anciently used by the Mexicans both in smoking and snuff, might become an important branch of agriculture, if the trade were free; but it is entirely prohibited, except in a few licensed spots, or rather is grown only by the government. *Indigo* is very little cultivated in Mexico; and the plantations along the western coast do not raise what is sufficient for the few manufactures of home cotton cloth. The article is annually imported from Guatimala, where it is raised in considerable quantities.

The domestic animals of Mexico were very few before the conquest. The Mexicans were not acquainted with the Llama, which was confined to the southern hemisphere; and they made no use of the wild sheep of California, or the goats on the mountains of Monterey, or the wild oxen in the vicinity of Rio del Norte. Dogs were used in some of the northern tracts in the carriage of tents, as in Siberia; and the flesh of a mute species of these animals, named the Techichi, was employed as food. A numerous class of the inhabitants named Flamama, were compelled to labour as beasts of burden, and to pass their lives on the highway under loads from 66 to 88 lbs. weight. But, since the middle of the 16th century, all the most useful animals of the old Continent, oxen, horses, sheep, and hogs, have multiplied surprisingly in all parts of New Spain, and especially in the vast plains of the Provincias Internas: nor have they at all degenerated in the New Continent, according to the fanciful hypothesis and rash assertions of *Buffon*. Numerous herds of *horned cattle* feed in the finest pastures along the eastern coast, particularly at the mouths of the rivers Alvarado, Guasacualco, and Panuco. The natives make little use of milk, butter, or cheese, and it is only among the mixed casts that the latter is in request. The *horses* of the northern provinces, and particularly of New Mexico, are not less celebrated than those of Chili. These animals wander wild in the savannahs of the Provincias Internas, and numbers are exported to Natchez and New Orleans. Many Mexican families are said to possess from thirty to forty thousand head of horses and oxen. *Mules* are still more numerous. More than 5000 are employed as an object of luxury, or in the carriages of the city of Mexico; and the commerce of Vera Cruz alone occupies annually about 70,000 of these animals, multitudes of which perish on the highways from the excessive fatigues of their journeys. The rearing of *sheep* has been strangely neglected, although they might easily be made to change their climate with the seasons, without at all interfering with the agriculture of the country. It is remarkable that neither the common *hog*, nor the *poultry*, which are found in all the islands of the South Sea, were known to the ancient Mexicans. The former have been introduced both from Europe and the Philippines, and have multiplied amazingly on the central table land. Before the arrival of the Spaniards, some of the more civilized tribes reared a few turkeys, pheasants, ducks, and moor hens about their houses; but now the different varieties of hens, particularly those of Mosambique, of which the flesh is black, have become common wherever colonies have settled. The *goose* is the only species of European poultry which is no where to be found in Spanish America.

The rearing of *silk-worms* was introduced by Cortez soon after the taking of Mexico; and considerable quantities of silk were produced in different provinces. But the injudicious restrictions imposed by the government on the native manufactures, and the interest which the Philippine company had in the sale of Asiatic silks to the Mexicans, have almost annihilated this branch of colonial industry. There are several indigenous caterpillars in New Spain, from which an inferior silk, called *Misteca*, is procured, which was an object of commerce even in the time of Montezuma, and of which handkerchiefs are still manufactured in the intendancy of Oaxaca. *Bees* are an object of attention in New Spain, chiefly for the sake of their wax, of which so great a quantity is consumed in the Catholic worship. One species, peculiar to the New Continent, has no sting, or at least so feeble a weapon as to produce no sensible injury; and from this circumstance they are known in the Spanish colonies by the name of Angelitos, *little angels*. The *Cochineal* insect has been reared in New Spain from the most remote period; but, in consequence of the vexations to which the natives were exposed in the beginning of the conquest, this branch of Indian industry became almost entirely neglected, except in the intendancy of Oaxaca. In the rainy seasons, the Indians make their cochineal insects travel to drier regions, by carrying them in baskets covered with palm-leaves.

The principal fisheries on the coasts of New Spain, are the whale and pearl fisheries. The western coast of Mexico, especially that part of the great ocean situated between the gulf of Bayonna, the three Mary Islands, and Cape St. Lucas, abounds in *spermaceti whales*, or cachalots. Till 1788, the whale fishers frequented the coast of Chili and Peru; and seldom above a dozen of these vessels doubled Cape Horn annually. But, since the voyage of Colnet to the Gallipagos made known the abundance of cachalots in the great ocean to the north of the equator, more than 60 vessels have been seen there under the English flag alone. One of the large cachalots will yield 125 barrels of spermaceti, eight of which forming a tun, used to sell in London from 80*l.* to 100*l.* sterling; yet the Spanish Mexicans make no attempt to share in this profitable pursuit. One cause of this neglect may be, that tapers of bees-wax only are permitted to be used in the churches, and spermaceti therefore is not in much request in New Spain; but it is also certain, that the sloth of the colonists prevents them from engaging in so laborious an employment. *Pearls* are procured in greatest abundance between the islands of Cubagua and Coche, and the coast of Cumana, at the mouth of the Rio de la Hacha, in the gulf of Panama, and on the eastern coast of California.

The ancient Mexicans were acquainted with the process of weaving cotton; and, soon after the conquest, the manufacture of cloth from the wool of European sheep was introduced into the country. But the Spanish government, though never actually prohibiting the establishment of manufactures in their colonies, have always discouraged those which were supposed to interfere with the demands for the same articles from the mother country. Notwithstanding all obstacles, however, many settlers from Spain have carried to the new continent the industry of their native provinces. The manufacture of coarse stuffs can easily be carried on at a low rate, where the raw materials are found in abundance; and the prohibition of commerce with neutrals, during the late hostilities throughout Europe, favoured greatly the making of *calicoes*, *fine cloths*, and other articles of luxury. The oldest *cloth* manufactures are those of Tezcuco, established in 1592, which, by degrees, passed entirely into the hands of the Indians and Mestizoes of Queretaro and Puebla. In these establishments there is great imperfection in many of the technical processes, particularly in that of dyeing. The workmen are treated in a great measure like slaves, being shut up all the week as in a prison, and flogged unmercifully for the smallest trespass. Though free, they are subjected to this constraint, by being kept continually in debt to their employers, who take care to furnish them with opportunities of spending their gains in drunkenness, and thus acquire a right to confine them at work, as the necessary step for procuring payment. Little *silk* is now manufactured in New Spain, and only a few stuffs of *cotton*, mixed with silk. Neither are there any manufactories of flax, or hemp, or paper. The manufacture of *tobacco*, which is a royal right, is very considerable; and in one great manufactory of segars at Queretaro, 3000 people are employed. The manufacture of hard *soap* is a considerable article of commerce at Puebla, Mexico, and Guadalaxara, and is greatly facilitated by the quantities of soda found in most parts of the table land of New Spain. The town of Puebla was formerly much celebrated for its manufactories of *delf-ware* and *hats*; but the former article has been much neglected of late years, in consequence of the low price of the stone-ware imported from Europe. The manufacture of *powder* is a royal monopoly; but immense quantities, (nearly three-fourths of the whole that is consumed in the country,) are made and sold in a contraband manner. One of the most extensive of the Mexican manufactures is that of *plate*; and, in the smallest towns there are gold and silversmiths, in whose shops workmen of all casts are employed. The academy of fine arts in the capital has diffused a taste for beautiful antique forms; and services of plate to the value of 200,000 francs have been manufactured in that city, which might rival in point of elegance and workmanship, the finest in Europe. The *coining of money* in the mint of Mexico is little else than a manufacturing establishment. It was established in 1535, and was first carried on by contract with individuals; but, since 1733, is entirely placed under the officers of government. Between 350 and 400 workmen are employed in this business; and so great is the number of machines, that, without any extraordinary exertion, they are able to coin annually thirty millions of piastres. It is computed by M. Humboldt, that all the silver produced in all the mines of Europe together every year, would not suffice to employ this extensive work above fifteen days; and that from this mint, since its establishment, has issued coin to the value of 408,000,000*l.* sterling. The produce of the manufacturing industry of New Spain is computed by the same author at 7 or 8 millions of piastres, (1,470,000*l.*, or 1,680,000*l.* sterling,) per annum.

The interior and coasting trade of Mexico is greatly impeded by the want of navigable rivers and artificial canals. The Rio de Santiago, which traverses the most populous part of the country, through a course of 170 leagues, might be rendered navigable at a moderate expense; and canals might be opened through the valley of Mexico; but the great lines of communication between the capital and the principal sea ports can never be improved by natural or artificial navigations. The town of Mexico forms the central point of the interior commerce; and the whole surrounding table land may be travelled by wheel-carriages in all directions; but, from the bad state of the roads, beasts of burden are preferred. The communication with the coasts is still more difficult; but means are said to be recently employed for facilitating the conveyance of goods both from Acapulco and Vera Cruz. The objects of this interior commerce are the exchange of goods between the different provinces, particularly between Mexico and the *provincias internas*; several productions from South America, conveyed through the country for exportation; and the articles which are exported or imported at the two great ports of Acapulco and Vera Cruz. As the inland provinces enjoy, in a great measure, the same climate, and consequently possess the same productions, it is chiefly the consumption of commodities by the mines which creates the interior commerce; but, as the crops of maize are seldom equally productive over so vast an extent of country, the conveyance of this necessary article from one place to another constitutes a considerable traffic. Thousands of mules, from Chihuahua and Durango, arrive every week at Mexico with bars of silver, hides, tallow, flour, and some wine, and take back, in return, woollen cloth of native manufacture, iron, steel, mercury, and goods from Europe and the Philippines. In time of war, when the navigation round Cape Horn becomes more hazardous, much of the cocoa of Guayaquil, the copper of Guasco, and the indigo of Guatimala, pass through the isthmus of Mexico to be shipped at Vera Cruz.

The foreign commerce of Mexico is naturally divided into that of the South Sea, and that of the Atlantic Ocean. The latter experiences great disadvantages from the want of commodious sea-ports; and almost all its operations have for centuries been concentrated at Vera Cruz, which is rather a bad anchorage than an actual harbour. The eastern coast, besides its sand banks, at all times is subject to violent hurricanes during the winter half of the year, and to the formidable yellow fever during the summer season. On the western coast are two magnificent ports, San Blas and Acapulco, the last of which is counted one of the most admirable basins in the world. But tremendous hurricanes blow on this coast during the months of July and August; and, even in September and October, the two fine harbours now mentioned are difficult of access. The principal articles of exportation at Vera Cruz, (exclusive of cocoa from Guyaquil, and indigo from Guatimala,) at an average of several years, are—

Gold and silver in ingots, coin and wrought plate, to the value of	£3,570,000
Cochineal	504,000
Sugar	273,000
Flour	63,000
Mexican indigo	43,680
Salted provisions, and other eatables	20,000
Tanned hides	16,800
Sarsaparilla	18,900
Vanilla	12,600
Jalap	12,600
Soap	10,500
Campeachy wood	8,400
Pimento of Tabasco	6,900

The articles of importation are—

Linen, cotton, woollen cloth and silks, to the value of .	£2,310,000
Paper	210,000
Brandy	210,000
Cocoa	210,000
Mercury	136,500
Iron	126,000
Steel	42,000
Wine	147,000
Wax	63,000
The average value of the whole exportation	4,620,000
Ditto, importation	3,150,000
Commercial circulation .	£7,770,000

The commerce of the western coast is confined to the Manilla galleon; the coasting trade with Guatimala and San Blas; and a few vessels annually dispatched to Guyaquil and Lima. The oldest and most important branch of the trade of Acapulco, is the exchange of the precious metals of Mexico for the merchandize of China and the East Indies. A single galleon, from twelve to fifteen hundred tons, sails from Manilla about the end of July with the south-west monsoon, bringing a cargo of muslins, printed calicoes, coarse cotton shirts, raw silks, and China silk stockings, jewelleries from Canton or Manilla, spices, and aromatics; and generally accomplishing the voyage in three or four months. The value of the cargo is limitted by law to half a million of piastres, (105.000*l.* sterling) but generally amounts to three or four times that sum. Of this lucrative merchandize the merchants of Lima have the greatest, and the ecclesiastical corporations the next highest share; and it is generally purchased with so much avidity, chiefly by a few great houses in the capital, that sometimes the whole sales are completed before the arrival of the galleon has been known at Vera Cruz. The return cargo consists of bars of iron, a little cochineal, cocoa, wine, oil, Spanish wool, and principally of the precious metals, to the value of a million of piastres. A number of passengers, particularly monks sent from Spain and Mexico to the Philippines, generally go with the galleon to Manilla, which sails in February or March, and by means of the trade winds accomplishes its long voyage in 50 or 60 days. A vessel is also dispatched annually from Manilla to Lima, one of the longest and most difficult of all voyages, as the ship must first discover the Mexican coast, and then steer southwards. The trade of Acapulco with the ports of Guayaquil and Lima is far from being active; and consists chiefly in the importation of copper, oil, Chili wine, a small quantity of sugar and quinquina (bark) from Peru, and cocoa from Guayaquil, sending thither in return a few woollens, a little cochineal, and contraband goods from the East Indies. The length and difficulty of the navigation from Acapulco to Lima, are the great obstacles to this trade between Mexico and Peru. The passage is peculiarly difficult from north to south; and often more time is required to sail the 210 marine leagues from Guayaquil to Callao, than to pass from Acapulco to Manilla through a course of 2,800 leagues. The chief hazards and delays arise from dead calms, violent hurricanes, and strong currents among the Gallipago islands. Notwithstanding the excellence of the ports on the west coast of Mexico, the coasting trade is extremely languid; and neither the spermaceti whale-fishery, nor the beaver fur-trade from Nootka, has been able to arouse the Spanish energies. The customs are not uniform in the different ports of the Spanish colonies, and are distinguished into royal and municipal duties. *Free effects*, *i. e.* the produce of Spanish agriculture and manufactures, pay, on landing, 9½ per cent.; *contributable effects*, *i. e.* the foreign produce manufactured in Spain, pay 12½ per cent.; *foreign effects* pay 7 per cent. having previously paid 15 per cent. upon entering, and 7 upon leaving the ports of the mother-country.

The contraband trade of New Spain is very extensive, and is carried on principally by the ports of Campeachy and Vera Cruz. In time of war, when the communication with Spain is interrupted, and the government obliged to admit occasional commerce with neutrals, this trade is pursued with great facility, and often amounts to one-third of the whole regular commerce in time of peace.

Previous to the year 1778, the whole commerce of Spanish America was monopolized by the cities of Cadiz and Seville; but, at this period, fourteen other ports were opened to the productions of the colonies; and this arrangement has been attended by a regular increase of the public revenue. The state of commerce in New Spain has again been greatly changed since the year 1794; and the foreign goods required in that country are those of the greatest value, the finest cloths, muslins, silks, wines, and other liquors. The produce of its own mines has also considerably increased during the same period; and more specie is ready to pay for these higher priced commodities. About the commencement of the nineteenth century, the importation into Mexico, including the contraband trade of both coasts, amounted to 20 millions of piastres; and the exportations of its agriculture and manufacturing produce to 6 millions; but the mines produce annually 23 millions, of which 8 or 9 millions are exported on account of the king, leaving 15 millions to liquidate the excess of the import over the export trade; from which will remain about one million for the increase of specie in the country. "But, by allowing a free course to the national industry," says M. Humboldt, "by encouraging agriculture and manufactures, the importation will diminish of itself, and it will then be easy for the

Mexicans to pay the value of foreign commodities with the productions of their own soil. The free cultivation of the vine and the olive on the table land of New-Spain; the free-distillation of spirits from sugar, rice, and the grape; the exportation of flour, favoured by the making of new roads; the increase of plantations of sugar-cane, cotton, and tobacco; the working of the iron and mercury mines; and the manufacture of steel, will perhaps one day become more inexhaustible sources of wealth, than all the veins of gold and silver united. Under more favourable external circumstances, the balance of trade may be favourable to New Spain, without paying the account which has been opened for centuries between the two continents entirely with Mexican piastres."

The revenue of New Spain, which has increased in an extraordinary degree in the course of the 18th century, was estimated, about the beginning of the 19th century, at twenty millions of piastres, or 4,200,000*l.* sterling. Of this sum, five millions and a half arise from the produce of the gold and silver mines; four millions from the government monopoly of tobacco; three millions from the alcaoalas or customs; one million and a half from the Indian capitation tax; and the remainder, from the duty on the fermented liquor pulque, from the duty on imports and exports, from the sale of Papal indulgences, from the post-office profits, from the sale of gunpowder, from clerical benefices, from the sale of cards, from stamp duties, from the farming of cock-fighting, from duty on the sale of snow, &c. About one half of the whole revenue is consumed by the expenses of the administration; and of the other half, about one-third is remitted to other Spanish colonies; and two-thirds to the mother country.

Nearly one-fourth of the whole revenue is expended on the military defence of the country, in which about 30,000 troops are employed. Of these, only 10,000 are regulars: of which, about 4,000 cavalry, stationed in the presidios, or military posts, to check the incursions of the Indians, are remarkably active and hardy soldiers, and incessantly exposed to severe service. The greater part of the military establishment is composed of provincial militia, raised more for shew than use; and chiefly originating in the love of military titles and rank, among a few Spanish families and wealthy creoles. The situation and physical aspect of the country, render it easily defensible against the attack of an external enemy.

The accounts of the population of Mexico, at the period of its subjugation to the Spaniards, are founded on very vague conjectures, and have been, in some cases, obviously exaggerated. Around the capital of Mexico, and probably in the whole kingdom of Montezuma, (which, however, did not equal in surface the eighth part of the present kingdom of New Spain,) there is good reason to conclude, from the extensive ruins of towns and villages, that the population was formerly much greater than at present; but this great body of people were concentrated within a very small space; and it is now well ascertained, that the whole of the vast region, denominated New Spain, is much better inhabited than it was before the arrival of the Europeans. The augmentation of tithes, of the Indian capitation tax, and of all the duties on consumption; the progress of agriculture and civilization, and the appearance of the country covered with newly constructed houses, all give evidence of a rapid increase in every part of the kingdom. In those districts where the climate is hot and humid, there is so great mortality, chiefly among the children and young people, by tertian fevers, (which is greatly aggravated by the practice among the native tribes of abandoning the infected,) that the population makes no sensible progress; but, in the colder regions, which compose the greatest part of the kingdom, the proportion of births to deaths is as 190, or even as 200, to 100; and the average over the whole country as 170 to 100. From a variety of *data*, Humboldt estimates the whole population in Mexico, in 1808, at more than 6,500,000. The most destructive checks to the population are the *small-pox*, which used to produce dreadful ravages among the Indians, whose constitution seems to be ill adapted for cutaneous diseases; a kind of plague called *marlazahuatl*, which appears at intervals of 100 years, and spreads its ravages over the coldest and driest regions, but never affects the white inhabitants or their descendants; *scarcity of provisions*, sometimes approaching to famine, when any great drought or local cause has damaged the crop of maize or potatoes, and which is always attended by epidemical diseases; and formerly the *compulsory labours* in the mines. But by the introduction of the cow-pox, the progress of agriculture, and the abolition of the *mita*, or compulsion of miners, these checks are greatly abated, and the general population greatly on the increase. The addition made to the number of inhabitants in New Spain, by the arrival of new colonists from Europe, does not exceed, says M. Humboldt, 800 individuals annually.

The Mexican population, like that of the other Spanish colonies, consists of four great casts, viz. the Whites, the Indians, the Negroes, and the people of mixed extraction. But the first class is subdivided into two races, viz. the individuals born in Europe; and the Spanish Creoles, or whites of European extraction, born in America. The last is subdivided into three races, viz. the Mestizos, or descendants of whites and Indians; the Mulattoes, or descendants of whites and negroes; and the Zembos, or descendants of negroes and Indians. The Indians, or indigenous Americans, excluding those who have any mixture of European or African blood, have considerably increased during the last fifty years; and constitute, in general, about two-fifths of the whole population in New Spain. In some districts, as in the four intendancies of Guanaxuato, Valladolid, Oaxaca, and La Puebla, they amount even to three-fifths. This race are rarely to be found in the north of Mexico, and hardly ever met with in the provincias internas. Among these there must originally have been many different tribes; as, besides an immense number of dialects, there are twenty distinct languages still spoken among them; fourteen of which have been reduced to grammars and dictionaries, viz. the Mexican, or Aztec, the Otomite, the Tarasc, the Zapotec, the Mistec, the Maye or Yucatan, the Totonac, the Popolouc, the Matlazing, the Huastec, the Mixed, the Caquiquel, the Taraumar, the Tepehuan, and the Cora. Of these, the first is most widely diffused, extending through a line of 400 leagues, from the 37° of north latitude to the Lake of Nicaragua; and the second is next in point of extent. These Indians in general bear a resemblance to those who inhabit Canada, Florida, Peru, and Brazil, in their swarthy copper colour, flat smooth glossy hair, small beard, long eye, with the corner directed upwards towards the temples; prominent cheek-bones, thick lips, a squat body, an expression of gentleness in the mouth, contrasted with a gloomy and severe look. The Indians of New Spain have even a more swarthy complexion than the inhabitants of the warmest climates of South America, even though the former are clothed, while the latter are quite naked. The Mexicans, particularly those of the Aztec and Otomite races, have also more beard than the Indians of South America; and this would seem to be generally the case in proportion as they are removed from the equator. They are remarkably free from every kind of deformity, (which some writers ascribe to the great simplicity in which their ancestors had lived for so long a period;) and in those districts where the goitre or tumour in the thyroid gland prevails, the Indians, and generally their descendants the Mestizoes, are free from that affection. This freedom from natural deformities is more extraordinary among an agricultural race, than among the hunting and warlike tribes, in whose situation the feeble and deformed are more likely to perish, or to be exposed in their infancy, and may therefore be considered as more closely connected with their peculiar constitution and mode of life. They are likewise a long lived race, particularly those who are under European dominion; and would attain a still more advanced age, if they did not weaken their constitutions by intoxicating liquors. This is particularly the case with those who inhabit the valley of Mexico, and the environs of Puebla and Tlascala, where the agaue (of which the pulque or native wine is made,) is cultivated on a great scale; and likewise in the warm countries on the coast, where the sugar-cane is grown. The marks of old age, however, are rarely observed among them; as their heads never become grey, and their skin is little subject to wrinkles. It is not uncommon in Mexico, in the temperate zone of the Cordillera, to meet with natives, particularly women, who have reached 100 years of age, and who still retain their muscular strength entire. In the present degraded state of these native tribes, it is not possible to ascertain the genuine character of the race, which must unquestionably have suffered no small deterioration by the extinction of the higher ranks, the destruction of the ancient sources of knowledge, and the insulated and oppressed condition in which they are held. The Mexican Indian in his present state discovers no vivacity of manner or activity of mind, but is grave, melancholic, and silent, unless when he is under the influence of intoxicating liquors. Concealment of his motives and feelings, even in matters of indifference, is one of his leading characteristics; and as the progress of the passions is never discerned in his features, he appears (when he is excited) to pass from the utmost stillness of mind to the most violent commotion of spirit. The descendants of the ancient republicans of Tlascala still discover a considerable degree of energy and even of haughtiness in their character, and particularly among the pastoral tribes or Indios Bravos, (as the Spaniards call those who are not properly reduced under their dominion,) much more nobleness of mind and force of character are observable; but the agricultural Indian, or Mexican peasant, is patiently submissive under the vexations of the whites; and opposes them only by the resources of cunning, under the appearance of the most stupid apathy. In their intellectual character they appear as if altogether destitute of imagination; but after a little cultivation, discover great facility of apprehension, a talent for seizing the minutest distinctions, and a power of reasoning with remarkable coolness and method. In the imitative arts, and purely mechanical operations, they display a high degree of aptitude and acuteness; but have in general appeared to succeed in any of the fine arts, particularly in painting, more from application than from genius. Their amusements even partake of the same sedate and sombre character. Their music and dancing are terrific and melancholy; and, though the females would probably introduce a little more vivacity, yet, in the usual depressed state of savage and half civilized life, they are not permitted to join in these exhibitions, and are merely admitted to supply the male performers with liquor. In one particular, however, these Indians evince a refined and elegant taste, which would seem to betoken the remains of higher attainments, viz. in their universal love of flowers, and skilful arrangement of nosegays, herbs, and fruits. With regard to their political condition, they have derived few means of improvement from their European rulers. The great body of the people were indeed found by the Spaniards in a state of the utmost poverty, and subjection to their despotic princes and feudal chiefs; but their new masters, instead of alleviating, made haste to aggravate their oppressions; dragging them from their homes to work in the mines, or to carry the luggage of the armies, and appropriating to themselves, as a right of conquest, all that they possessed in lands or goods. Since the commencement, however, of the 18th century, their situation has become progressively better, and their interests have been taken under the protection of the intendants. A few of the great Indian families, or Caciques, who still remain, are entitled by the Spanish laws to share the privileges of the Castilian nobility; and they receive all the former homage which used to be paid to them by the inferior ranks. But their own privileges are more illusory than real; and, even where they have some authority as magistrates of the native villages, they are more oppressive than even the whites towards the tributary casts, and not at all superior to the lowest peasantry in point of knowledge or civilization. The Mexican Indians, when considered in a mass, present a picture of extreme misery; and scarcely any individuals are to be found among them who enjoy mediocrity of fortune. The greater part, banished into the more barren districts, and indolent from natural disposition, as well as discouraged by their political bondage, live in daily poverty; and even the few noble families who possess great plantations and vineyards, (to the value sometimes of 30,000*l.* or 40,000*l.*,) carefully conceal their wealth, generally going barefooted, and clothed in the same coarse garment with the lowest of their countrymen. The Indians are exempted from all direct imposts, but are subjected to a tribute or capitation tax, which has varied at different periods, and in different districts, but at present is usually eleven francs per annum. They pay also to the clergy ten francs for baptism, twenty for a certificate of marriage, twenty for interments, and from twenty-five to thirty in the form of voluntary offerings for masses, &c. They are deprived of the most important rights of citizens, by being counted as minors, under the tutory of the whites; so that every act which they sign, and every obligation which they incur beyond the value of fifteen francs, are declared null. They are kept in a state of complete insulation; prohibited from intermarriage with the whites; shut up in villages of their own; subjected to subaltern magistrates among themselves, who find their interest in perpetuating the ignorance and barbarism of the people; rendered incapable of commercial transactions; confined to the situation of common labourers or artisans; and thus completely excluded from all chance of advancing in civilization of manners, or acquisition of property. "Let the odious personal impost of the *tributo* be abolished," (says the enlightened Bishop of Mechoacan, in a memoir presented in 1799 to the Spanish monarch) "let the infamy which unjust laws have attempted to stamp on the people of colour be at an end;—let them be declared capable of filling every civil employment which does not require a special title of nobility;—let a portion of the demesnes of the crown, which are generally uncultivated, be granted to the Indians and the casts;—let an Agrarian law be passed for Mexico, similar to that of the Asturias and Gallicia, by which the poor cultivator is permitted to bring in, under certain conditions, the land which the great proprietors have left so many ages uncultivated, to the detriment of the national industry;—let full liberty be granted to the Indians, the casts, and the whites, to settle in villages, which at present belong only to one of these classes;—let salaries be appointed for all judges and all magistrates of districts;—these are the six principal points on which the felicity of the Mexican people depends."

The white inhabitants consist of whites born in Europe, called chapetones or gachupines, and those descended of Europeans in the Spanish colonies of America, or in the Asiatic islands, called Creoles. The laws allow the same rights to all whites; but the government, suspicious of the Creoles, has granted (or rather sold) public offices chiefly to the natives of Old Spain. Hence a perpetual hatred and jealousy exists between the Chapetones and Creoles; the meanest of the former counting themselves superior in blood, and having the chance of becoming superior in rank, to the most distinguished natives of the New Continent; and the latter, in contempt of this assumed pre-eminence, as well as in a spirit of alienation from a country which subjects them to such unworthy treatment, preferring the name of Americans to that of Spaniards. There are about 1,200,000 whites in New Spain, or a proportion of 16 to every 100 of the other casts; of whom not above 70,000 or 80,000 (a 70th part of the whole population, and only one to fourteen of the Creoles,) are natives of Europe. In all Spanish America, the word European is synonimous with Spaniard; and no Europeans, except such as are born in Old Spain, are admitted into the American colonies. The inhabitants of the more remote provinces, still conceiving the ancient power of Old Spain as predominant in Europe, regard the peninsula as the centre of civilization, and consider it as a mark of low extraction to be ignorant of the Spanish language. But in the capital of Mexico, the Creoles, being better acquainted with the present state of Europe, and instructed in French or English literature, fall into the contrary extreme; consider their own intellectual progress as superior to that of the peninsula; and prefer strangers from other countries before the Spaniards themselves. There is indeed considerable intellectual activity among the young Creoles, who apprehend the principles of science with great facility. At Mexico and Santa Fé the study of mathematics, chemistry, mineralogy, and botany, is very general, and the former city surpasses every other in the New Continent, not excepting those of the United States, in solid scientific establishments. The whites are also the exclusive possessors of great wealth, and nothing is more striking than the inequality of its distribution. There are many individuals, whose annual income, without any profit drawn from the mines, amounts to a million of francs, (41,670*l.* sterling;) and some of the great miners draw from that source alone an annual revenue of a million and a half of livres, (or 62,505*l.* sterling.) But the capitals of these monopolizers of money are by no means great in proportion, partly in consequence of the expensive mining operations in which they often engage, and the extravagant style in which they live.

There are fewer negroes in New Spain than in any of the European colonies under the torrid zone; and the whole kingdom is not supposed to contain above 6000 of that race, nor to receive above 100 annually of the 74,000 Africans who are exported every year to America and Asia. By the laws, there cannot properly be any Indian slaves in the Spanish colonies; but in Mexico, or in Peru, the Indios Bravos taken in the petty warfare, which is continually carried on along the frontiers of the provincias internas, are kept in dungeons, and treated as the most degraded bondmen. But all kinds of slaves are more under the protection of the law, and those laws are interpreted more in favour of liberty, in Mexico, than in any other European colony. A slave may compel his master to grant him liberty upon paying 1500 or 2000 livres, (62*l.* or 82*l.* sterling,) whatever may have been the amount of his original purchase money; or, if he can prove that he has been cruelly treated, he acquires his freedom by law, without any compensation to his proprietor.

The casts which spring from the mixture of these three races, amount nearly to 2,400,000. About seven-eighths of these are Mestizos, the descendants of a white and an Indian, and are distinguished by a pure white colour, a peculiar transparency of skin, small hands and feet, thin beard, and a certain obliquity of the eyes. They are of a milder character than the Mulattoes descended from whites and negresses, who are usually distinguished by the violence of their passions, and volubility of their speech. A Mestizo marrying a white man produces an offspring differing very little from the European race; but the children of a Mulatto and a white man are called quarterons, and the children of a quarteron female and Creole or European father, bear the name of quinterons. But a new alliance of this last mentioned cast with a white banishes all remains of colour. The descendants of negroes and Indian women are called Chinos or Zambos, though the latter denomination is usually confined to the children of a negro and mulatto, or a Chino female. All the casts of Indian or African blood preserve the odour peculiar to the perspirable matter of these races. The degree of whiteness of skin decides the rank which every one occupies in America; and a white who rides on horseback, though barefooted, accounts himself one of the nobility of the country. It thus becomes a very interesting point among them to estimate exactly the fractions of European blood which belongs to the different casts; and families, suspected of a mixed taint, frequently demand from the high court of justice a declaration of their whiteness. These declarations are said to be sometimes procured in cases not very obvious to the senses; but, when the colour of the skin is very repugnant to the judgment demanded, the sentence simply bears, "that such or such individuals may consider themselves as whites."

The inhabitants of New Spain have more science than literature. Mathematics are carefully taught in the university of Mexico, but still more so in the school of mines in that city; and New Spain can boast of having given birth to a celebrated self-taught geometrician, Don Joacquin Velasquez, who was born in 1732, and who rendered the most essential services to his country. Astronomy has long been a favourite subject of study in this country, and was successfully cultivated about the end of the eighteenth century by Velasquez abovementioned, and by Gama and Alzate. The last of these, a man of ardent genius, had great merit in exciting his countrymen to the study of the physical sciences; and, for a long time, encouraged a studious spirit among the Mexican youth, by the publication of his *Gazetta de Litteratura.* Gama, the friend and fellow-labourer of Velasquez, became, under great disadvantages, a well-informed astronomer, and published several excellent memoirs on eclipses, on Mexican chronology, and on the climate of New Spain. The principles of chemistry, which is known in the colonies by the name of new philosophy, are very generally understood among the Mexicans. In the botanical garden of Mexico, annual courses of lectures are delivered on botany; and several natives of New Spain, particularly M. Sesse and M. Echeveria, have distinguished themselves by their acquirements in this science. In the academy of the fine arts at Mexico, there is a more complete collection of casts than is to be found in any part of Germany; and, in this institution, instruction is communicated gratis to the youth of all descriptions, of whom several hundreds are assembled every evening, in large and well-lighted apartments, busily employed in drawing from the most elegant models. The good effects of this establishment are very visible in the architecture of the country, particularly in the symmetry of the buildings, the hewing of the stone, and the ornaments of the capitals and stucco relievos. There are edifices, not only in the capital, but also in the provincial towns, which would appear to advantage in the finest streets of Europe, and which are constructed at an expense often of a million or a million and a half of francs, or 41,670*l.* and 62,505*l.* sterling. An equestrian statue of King Charles IV. cast by M. Tolsa, professor of sculpture at Mexico, is considered as next in merit, of any similar work extant, to that of M. Aurelius at Rome.

The clergy in Mexico amount to the number of 10,000 individuals, of whom one-half are regulars, who wear the cowl; and, including lay-brothers and sisters, or servants, may be rated at 13,000 or 14,000. This number is much inferior to what has been generally supposed, and, in proportion to the population, is not the tenth-part of those in Old Spain, or in France before the Revolution. The ecclesiastical establishment in Mexico resembles that of Spain, with its full train of dignitaries. The inferior clergy are divided into three classes: namely, curas, who are parish-priests in those parts of the country where the Spaniards have settled; doctrineros, who have the charge of districts inhabitated by the Indians subject to the Spanish government; and missioneros, who are employed in teaching and converting the fiercer tribes, who resist the Spanish yoke, and live in the more remote regions. A great many of them suffer extreme poverty, while the revenues of some surpass those of many sovereign princes in Germany. The archbishop of Mexico possesses an income of 650,000 francs, or 27,085*l.* sterling, and several of the bishops not much less; while there are clergymen of Indian villages whose yearly income does not exceed 500 or 600 francs, from 20*l.* to 25*l.* sterling. Cortez complained, even in his time, of the extravagant luxury and scandalous lives of the canons; and requested that religeux, or regular monks, might be sent out in preference; but the advice was not followed.

Their labours among the natives have tended rather to change their ceremonies than their sentiments; and it has been the policy of the teachers, from the beginning, to tolerate, and even to reconcile with Christianity, as much as possible of the ancient system. The sanguinary spirit of the old rites is, indeed, abolished: but, otherwise, the Indians know little more of religion than the exterior forms of worship, in which, according to the Catholic ritual, they find one of their principal sources of amusement. The festivals of that church, the fireworks with which they are accompanied, the processions, dances, and fantastical dresses which are exhibited, interest the lower Indians in the highest degree and afford an opportunity for displaying all the peculiarities of the national character.

New Spain was formerly distributed into the following ten districts:—kingdom of Mexico, kingdom of New Gallicia, new kingdom of Leon, colony of New Santander, province of Texas, province of Cohahuila, province of New Biscay, province of Sonora, province of New Mexico, and the two Californias; and these divisions are still frequently used in the country. It is now divided into twelve intendancies, and three provinces, namely,

Under the temperate zone.	1.	Province of New Mexico.	North region.
	2.	Intendancy of New Biscay, or Durango.	
	3.	Province of New California.	North-west region.
	4.	Province of Old California.	
	5.	Intendancy of Sonora.	
	6.	Intendancy of San Louis Potosi.	North-east region.
Under the Torrid Zone.	7.	Intendancy of Zacatecas.	Central region.
	8.	Intendancy of Guadalaxara.	
	9.	Intendancy of Guanaxuato.	
	10.	Intendancy of Valladolid.	
	11.	Intendancy of Mexico.	
	12.	Intendancy of Puebla.	
	13.	Intendancy of Vera Cruz.	
	14.	Intendancy of Oaxaca.	South-west region.
	15.	Intendancy of Merida, or Yucatan.	

Some of these intendancies are ten, twenty, and even thirty times larger than others; while several of the least extensive contain above 100 times more inhabitants than the larger divisions. The following Table may be useful, as presenting in one view these striking inequalities of the distribution of Mexican population, even in the most civilized part of the kingdom.

Intendancies.	Extent in square Leagues.	Number of Inhabitants.	Inhabitants to the square League.
San Luis Potosi	27,821	331,900	12
Sonora	19,143	121,400	6
Durango or Biscay	16,873	159,700	10
Guadalaxara	9,612	630,500	66
Merida	5,977	465,700	81
Mexico	5,927	1,511,800	255
Oaxaca	4,447	534 800	120
Vera Cruz	4,141	156,700	38
Valladolid	3,447	476,400	273
Puebla	2,696	813,300	310
Zacatecas	2,355	153,000	65
Guanaxuato	911	517,300	568

The fundamental maxim of Spanish jurisprudence in Mexico and the other colonies is, to consider all these acquired dominions as vested solely in the crown, and as in a manner the personal property of the sovereign. This right is rested upon the bull of Alexander VI. which bestowed, as a free gift, upon Ferdinand and Isabella, all the regions that had been or should be discovered in America. From the Spanish monarchs all grants of land in that continent proceed, and to them they finally return. The leaders of the various expeditions, the governors of the different colonies, the officers of justice, the ministers of religion, are all appointed by their authority, and removable at their pleasure. The colonists are entitled to no privileges independent of the sovereign; and even in the largest cities the rights of the citizens are merely municipal, and limited to the regulation of their own internal commerce and police. All political power, every thing relating to public government, centres in the crown, and in the officers whom it has nominated. The viceroy of New Spain not only represents the person of the sovereign, but possesses all his regal prerogatives in their utmost extent, and exercises supreme authority in every department of government, civil, military, and criminal. He has the sole right of nominating to the principal offices, and of supplying those which are in the king's gift till the person whom he appoints shall arrive. His court is formed upon the model of that of Madrid, and displays an equal or even a superior degree of magnificence and state. He is aided in his extensive government by officers and tribunals resembling those of Spain; and though some of these are appointed by the sovereign, they are all subject to the viceroy's command, and amenable to his jurisdiction.

The administration of justice is vested in tribunals called audiencias, formed upon the model of the Spanish court of chancery. One of those, consisting of a number of judges, proportioned to the extent of the district, is established in every province, and takes cognizance both of civil and criminal causes. The viceroys are expressly prohibited from interfering in the decisions of these courts; and in some cases the audiencias may bring his political regulations under their review, and present remonstrances on the subject; or, finally, lay the matter before the king and the council of the Indies. Upon the death of a viceroy, the supreme power is vested in the audiencia of the capital till a successor be appointed, and the senior judge, assisted by his brethren, exercises all the functions of the vacant office. The sentences of these courts are final in every litigation concerning property of less value than 6000 pesos; but when the subject in dispute exceeds that sum, their decisions may be carried by appeal to the council of the Indies—a court which was instituted by Ferdinand in 1511, and brought into a better form by Charles V. in 1524. Its jurisdiction extends to every department of government in Spanish America, and all laws and regulations respecting the colonies must be approved by two-thirds of the members. All the officers nominated by the king are conferred in this council; and to its inspection every person employed in America, from the highest to the lowest, is held accountable. In this council the king is always supposed to be present, and its meetings are always held where he resides.

The leading object of the Spanish government has always been, to secure the productions of the colonies to the parent state, by an absolute prohibition of all intercourse with foreign nations. All that the colonies yield must be conveyed to Spanish ports, and all that they consume must flow from the mother country. No foreigner can enter the colonies without express permission; no vessel of a foreign nation is admitted into their harbours; and no inhabitant is permitted to trade with them upon the pain of death. More liberal measures have been gradually adopted; but much still remains to be done, which will probably be delayed till the colonies declare themselves independent, and consult for their own prosperity.

The ancient history and early institutions of Mexico are involved in almost impenetrable obscurity, and all that has yet been advanced on the subject, rests on no surer foundation than certain hieroglyphical paintings, which admit of the most various interpretations. The authenticity of these documents themselves is sufficiently questionable; and it is impossible to ascertain that they are either original, or faithful copies of originals, and not the fabrications of the Spanish monks, who are known (upon the usual principle of Roman Catholic missionaries) to have commended the truths of Christianity to their Indian subjects, by tracing a resemblance between the new doctrines and the old superstitions of the natives. The knowledge of events among the ancient Mexicans, was preserved by means of those knots and threads of various colours, called by the Peruvians *quippus*, and said to have been found also among the Canadians and Chinese. These very imperfect and unintelligible records were superseded by the use of writing and hieroglyphics only about A. D. 648, from which period alone, therefore, any tangible documents can be dated. These symbolical figures, however, though of a more permanent character than the knotted threads, are still of little service without the principles of their interpretation, which are very doubtfully preserved. But supposing both the record and the exposition to be undoubtedly established, there are only a few fragments in existence upon which the ingenuity of the antiquary can be exercised. These paintings being considered as monuments of idolatry deserving to be destroyed, were ordered by Zummaraga, the first bishop of Mexico, to be carefully collected, and committed to the flames. Whatever knowledge of remote events these rude monuments contained has thus been almost entirely lost; and the whole of our information must be derived from traditions, and the few remnants of those historical symbols which have escaped destruction. Collections of these fragments have been deposited in the libraries of the Vatican, Veletri, Vienna, Dresden, Berlin, Paris, and (as some have conjectured) of Oxford; but the most authentic and valuable are said to be those which are printed in Purchas's pilgrims These paintings are done on skins, cotton cloth, a kind of pasteboard, or on the bark of trees. These manuscripts were neither composed of separate leaves nor rolls, but generally folded in a zigzag manner like fans, with two tablets of light wood pasted at the ends. The manuscripts brought to Europe bear a great resemblance to each other, and are chiefly remarkable for great strength of colouring. The figures are mostly dwarfish in respect of the body, and remarkably incorrect in point of drawing. The heads are of an enormous size, the bodies extremely short, and the feet so long in the toes as to resemble the claws of a bird. The heads are always drawn in profile, while the eye is placed as if the figure presented a full view; and the noses are of a most disproportionate size. "Every figure," in short, (in the words of Dr. Robertson,) "of men, of quadrupeds, of birds, as well as every representation of unanimated nature, is extremely rude and awkward. The hardest Egyptian style, stiff and imperfect as it was, is more elegant. The scrawls of children delineate objects almost as accurately." Their uncouth forms may be considered, indeed, with M. Humboldt, as equivalent to the bad hand-writing of our literati; or as necessarily retained, as established symbols, in more civilized periods. But the confusion and obscurity of the whole system defy all explication; and leave no other source of information than those originally uncertain traditions in regard to the history of the nation.

According to these traditions, the Mexican empire had not been of long duration previous to the Spanish invasion. Their country, as they relate, was originally possessed by small independent tribes, whose manners and mode of life resembled those of the rudest savages. But, at a period nearly corresponding with the beginning of the 10th century of the Christian era, several tribes arrived by successive migrations from unknown regions towards the north and north-west, and being more civilized than the original inhabitants of Anahuac (the ancient name of New Spain) began to introduce the arts of social life. The Toultecs appeared first in the year 648; the Chichimecks in 1170; the Nahualtecs in 1178; the Acolhuecs and Aztecs in 1196. These nations, speaking the same language, and apparently proceeding from the same quarter, described themselves as expelled from a country lying to the north-west of the river Gila, brought with them paintings, which indicated the events of their migration; and gave the names of the cities which they had left to those which they first built after their arrival, namely, Huehuetlapallan, Aztlan, Teocolhuacan, Amaquemacan, Tehuajo, and Copalla. But their real origin still remains an inexplicable enigma in history. They are conjectured by M. Humboldt to have proceded from Tartary or China, and to have been a portion of those Hiongnoux, who, according to the Chinese historians, emigrated into the northern parts of Siberia, and part of whom pushed through Asia into Europe under the name of Huns. The era of the Toltec migration 544, about 100 years before their arrival in Anahuac, corresponds with the period when the ruin of the dynasty of Tsin occasioned great commotions among the nations in the east of Asia. But for all this, there is, in fact, no other ground than mere conjecture; and out of 83 American languages, carefully examined by competent judges, only 170 words have been found which could be traced to the languages of the old continent, namely, to those of the Mantchou Tartars, the Monguls, the Celts, the Biscayans, the Copts, and the natives of Congo. From whatever quarter they procceded, they are said to have brought with them the arts of hieroglyphic painting, of casting metals, and cutting the hardest stones. They introduced the cultivation of maize and cotton, built cities, made roads, and constructed pyramids. They had a solar year more perfect than that of the Greeks and Romans; and had a form of government, which shewed that their progenitors had experienced great vicissitudes in their social state. The last mentioned tribe, about the beginning of the 13th century, advanced from the city of Aztlan to the plains around the great lake of Mexico, where, after several years occupation of the spot, they founded the city of Mexico; but were still unacquainted with regal government, and were ruled in peace, or commanded in war, by such as were most entitled to pre-eminence by their wisdom or valour. But at length the supreme authority centered in one person; and, at the time of the conquest, Montezuma was the ninth monarch who had swayed the Mexican sceptre, not by hereditary right, but by popular election. This recent origin of the Mexican nation (which is indeed confirmed by their own want of historical traditions) is not easily reconciled with the high degree of civilization, which the Spanish accounts represent them to have attained at the time of the conquest; and it is highly probable that the splendid descriptions of their government and manners are considerably exaggerated. These accounts also are obviously so contradictory, and apparently so inaccurate, that no correct estimate can be formed of the state of society and progress of the arts in the Mexican empire, when it fell under the power of Spain. The extent even of the empire was represented by the conquerors in a very delusive light; and the dominions of Montezuma were spoken of as stretching over all the provinces of New Spain, from the Northern to the Southern Ocean. But a great part of the mountainous country north of the river Santiaga, was possessed by the Otomites and Chichemecs, a race of ferocious and uncivilized hunters, none of whom recognized the supremacy of the Mexican monarch. These tribes occupied the plains of Zelaya and Salamanca, now admired for their fine cultivation; and frequently extended their ravages as far as Tula, on the northern bank of the valley of Tenochtitlan. Even in the interior and level country there were several cities and provinces which had never submitted to the Mexican yoke; and the territory denominated Anahuac, between the 14th and 21st degrees of latitude, contained, besides the Aztec empire of Montezuma, the small republic of Chalollan, (Cholula,) within less than 20 leagues of the capital, and subjected to the Mexican crown only a short time before the arrival of the Spaniards; Tlaxcallan (Tlascala,) another independent and hostile state; Tezcuco (Tepeaca) and Mechoacan, two considerable kingdoms, whose frontiers reached within 30 or 20 leagues of Mexico, and the latter of which was remarkable for its implacable enmity to the Mexican name. The empire of Montezuma was thus bounded towards the east by the rivers of Guasacualco and Tuspan; and towards the west by the plains of Soconusco and the port of Zacatula; comprising only the modern intendancies of Vera Cruz, Oaxaca, Puebla, Mexico, and Valladolid, an area of about 15,000 square leagues.

The progress of civilization and state of society in this empire may be estimated by the following facts. 1. *The right of private property was fully understood;* and both property in land and property in goods might be transferred by barter, or descend by inheritance. Land was held by various tenures; by some it was possessed by full right, and it descended to their heirs; but by others it was enjoyed along with some office or dignity with which it was acquired or lost. These two modes of occupation were deemed noble, and were peculiar to the highest class. The great body of the people had only a share in the produce of a common tract of land, which was measured out in every district, according to the number of families, and was cultivated by the joint labour of the whole community; its produce deposited in a common storehouse, and divided among them according to their respective exigencies. 2. *The cities were numerous*, well inhabited, and, though doubtless greatly overrated in point of population and splendour, in the accounts of the conquerors, yet appear to have been of such importance as to indicate a considerable degree of progress in the arts of social life. The capital seems at least to have contained 60,000 inhabitants. 3. *The separation of the professions* had taken place to a considerable extent. The function of the mason, the weaver, the goldsmith, the painter, and several other trades, were carried on by different persons, who were regularly instructed in their respective crafts; and, by means of assiduous application to one object, they attained a degree of neatness and perfection beyond what could have been expected from the rudeness of their tools. Their various productions were brought to markets regularly held in the cities, and exchanged in the orderly intercourse of commerce. 4. *The distinction of ranks* was established by very wide intervals. The great body of the people was placed in a very humiliating state. A considerable number, named Mayeques, were attached to the soil, which they were bound to cultivate, and with which they were conveyed from one proprietor to another. Others were held in the most rigorous condition of domestic servitude, and their lives were deemed of so little value, that the murderer of any of them was not subjected to any punishment. Even those who were considered as freemen, and had their share of a common tract of land as above mentioned, were treated by the haughty nobles as beings of an inferior species. The nobles themselves were divided into various classes, with their peculiar titles, some of which descended with their lands to their families, and others were annexed to particular offices, and conferred for life, as marks of personal distinction. The respect due from one rank to another was prescribed with the most ceremonious accuracy, and incorporated itself with the expressions and idioms of the language, which is said to abound in terms of courtesy. The people were not allowed to wear the same dress, or to dwell in houses of the same form with those of the nobles, or to accost them without the most submissive reverence, while, in the presence of their sovereign, they durst not lift their eyes from the ground or look him in the face. The nobles themselves, when admitted to an audience with the monarch, were obliged to enter bare-footed, in mean garments, and with forms of homage approaching to adoration. 5. There appear to have been many *established laws and customs* circumscribing the power of the crown, previous to the election of Montezuma, who subverted the original system of government, and introduced a pure despotism. There were thirty nobles of the highest order, each of whom had about 100,000 people in his territories; and subordinate to these there were about 3000 nobles of a lower class. The jurisdiction of the crown was extremely limited, as in the times of feudal policy in Europe; and the nobles guarded their extensive privileges with the utmost jealousy, against the encroachments of the crown. The king could not determine concerning any point of general importance, such as making war and disposing of the revenue, without the approbation of a council composed of the principal nobility. The right of electing the sovereign seems to have been originally vested in the whole body of the nobles; but was afterwards committed to six electors. Generally, the choice fell upon some individual who was sprung from the royal family; and to the successive choice of able and warlike princes may be ascribed the extraordinary power which the empire attained in so short a period of time. Under Montezuma, the splendour of the Mexican court resembled the magnificence displayed in the ancient monarchies of Asia. 6. Considerable order and regularity were manifest in the *internal administration and police* of the empire. The crown exercised complete jurisdiction over its immediate vassals; and judges were appointed for each department, whose decisions are said to have been formed with a degree of order and equity resembling the practice of highly civilized societies. 7. For the support of government, *taxes* were laid upon land, upon the acquisitions of industry, and upon commodities of every kind; and were levied according to equal and established rules; but, as the use of money was unknown, these taxes were all paid in kind, and the public storehouses were filled with every kind of natural production, manufactured articles or works of art, from which the emperor supplied his attendants in peace, and his armies during war, with food, clothing, and ornaments. People of inferior rank, neither possessed of land, nor engaged in commerce, instead of taxes, were bound to render personal service, in cultivating the crown lands and carrying on public works. 8. Several *regulations of police* among them indicate a considerably improved state of government. The relays of couriers stationed at proper intervals, to convey intelligence from one part of the empire to the other; the structure of the capital in a lake with artificial dykes and long causeways erected in the water; the plan of their aqueducts, or conduits for conveying a stream of fresh water into the city along one of the causeways; the appointment of a number of persons to clean the streets, to light them by fires, and to patrole as watchmen during the night, are all marks of high refinement and order. 9. Their progress in various *arts* evinces most decisively the civilized habits which they had attained. They represented men, and animals, and other objects, by such a disposition of various coloured feathers, as is said to have produced all the effects of light and shade, and their ornaments of gold and silver have been also described as equally curious. At the same time, it is to be kept in mind, that the specimens of these ornaments and utensils deposited in the cabinet of the king of Spain, are affirmed to be very coarse and uncouth representations of the human form and other objects, and to be destitute both of grace and propriety.

The earliest and one of the most authentic specimens of those paintings, by means of which the Mexicans supplied their want of written records, was published, as has been noticed, by Purchas, in 66 plates, divided into three parts: the first of which (according to explanations obtained from the natives) contains the history of the Mexican empire under its ten monarchs; the second represents the tribute which each conquered town paid into the royal treasury; and the third is a code of their domestic, political, and military institutions. But, if we may judge from the specimens and explanations given by M. Humboldt in his American researches, nothing can well be conceived more clumsy in execution, more vague in the interpretation, or more uncertain as historical records, than these boasted devices. The more simple of these hieroglyphics represent a town by the rude delineation of a house with certain emblems, sometimes natural objects, and sometimes mere artificial figures, to distinguish one from another. Some of them are mere fanciful figures. A monarch, for instance, who had extended his empire by force of arms, is represented by a painted target, ornamented with darts, placed between his figure and the emblems of the towns which he had subdued. In designating numbers, they had reached the farther step of mere conventional signs, expressing a small number by so many circles as units, but assigning to large integral numbers their peculiar marks. A small standard or flag, for instance, represented 20, a feather 400, a sack 8000; and so on, says Clavigero, as far as 48,000,000. A flag, divided by two cross lines, and half coloured, denoted 10; and if three quarters were coloured it signified 15. A flag followed by three dots or points expressed 23, &c.

Their mode of computing time is considered as a more decisive evidence of their progress. Their civil year was a solar year of 365 days, and consisted of 18 months, each containing 20 days. The five intercalary, or rather supernumerary days, were considered as unlucky days, on which no work should be done, or sacred rite performed, and were devoted solely to amusement. The day was reckoned to begin at sun-rising, and was divided into four intervals, by the rising and setting of the sun, and its two passages over the meridian. Each month of 20 days was divided into four weeks of five days each. Thirteen years formed a cycle, to which they gave a particular name, and four of these constituted a period of 52 years, which they denoted by another term. Two of these periods of 52 years formed what they called an old age. At the end of 52 years, 13 days were intercalated to bring their time up to the seasons, which makes their year agree with the Julian period of 365 days and 6 hours, and discovers a considerable degree of philosophical accuracy.

A variety of considerations concur, on the other hand, in proving the civilization of the Mexicans to have been extremely imperfect. Their mode of carrying on war was altogether savage, and they fought chiefly to gratify their vengeance, by shedding the blood of their enemies. They estimated the glory of a victory by the number of prisoners; and all the captives were invariably butchered and devoured with the most barbarous excesses. Their funeral rites were equally bloody; and, on the death of any distinguished person, a certain number of his attendants were put to death, and buried in the same tomb.

Their agricultural productions were by no means so abundant as to furnish a plentiful subsistence to the nation; and various precautions were employed to prevent a rapid increase of population. There was little intercourse between the different provinces of the empire; and scarcely any roads to facilitate such communications. They were destitute of money, and of any universal standard for estimating the value of commodities. All their commerce was carried on by barter, except that nuts of cocoa (from which chocolate, the favourite drink of the higher ranks, was made,) had begun to be used as a medium of exchange.

Their architecture was altogether rude and imperfect; and, even in their larger cities, the houses were mere huts of turf and stone, thatched with reeds, and without windows. Nor do the public buildings and houses of the nobility appear to have been constructed of more durable materials.

The religion of the ancient Mexicans was of the most gloomy and revolting description. Their divinities were represented as delighting in vengeance, and were exhibited under the most detestable and horrifying forms. Their temples were decorated with the figures of the most ferocious and destructive animals with which they were acquainted; and fear was the only principle instilled into the minds of their votaries. The most rigid mortifications and excruciating penances were the means employed for appeasing the wrath of the gods; and the worshippers sprinkled the altars, as they approached, with blood, drawn from their own bodies. Human sacrifices were accounted the most acceptable of all offerings, and every captive taken in war was devoted as a victim to the deity. The head and heart were allotted to the idol, and the body carried off as a feast for the offerer and his friends. Under the influence of such barbarous superstitions and bloody spectacles, the spirit of the Mexicans became unfeeling, and their manners in many respects not less ferocious than those of the most savage tribes, who were far behind them in point of general civilization. Without losing the fiercer features of the wandering and independent Indians, they had fallen into many of the evils which attend the formation of political societies and large communities. When the Spaniards made the conquest of Mexico, they found the people in that state of abject submission and poverty which usually accompany a despotic government and feudal institutions. The higher classes alone possessed the more fertile lands—the governors of provinces indulged with impunity in the severest exactions—and the cultivators of the soil were every where degraded. The highways swarmed with mendicants; and, from the want of large quadrupeds in the country, thousands of the lower orders were employed as beasts of burden in conveying the maize, cotton, hides, and other commodities sent from the more remote provinces to the capital, in the payment of tribute.

There are few remains of Mexican antiquities to be found in the country. Even the hieroglyphic paintings are now so scarce, that the greater part of the well-informed persons who reside there have never seen any. Cortes, at the conquest, destroyed the temples, broke the idols, and buried three masses of stone, which were too large to be destroyed, that every thing belonging to the ancient rites might be concealed from the eyes of the people. Some of these stones have been recently discovered, and particularly one of an immense size, covered with sculpture, relative to the calendar. This was dug up in 1790, in the great square of Mexico, among the foundations of the temple of Mexitli. Its actual weight is 24 tons; and as no mountain within eight or ten leagues of the spot furnishes the same kind of porphyry, it must have been conveyed with immense labour to the foot of the sacred edifice. Another of a cylindrical form, and covered with figures in relief, was also found upon levelling the great square in Mexico, and is supposed to be the stone of sacrifices usually placed on the summit of the teocallis; but is conjectured by M. Humboldt to correspond rather with the account given of large stones, upon which the braver prisoners were condemned to sustain the combat of gladiators with a succession of Mexican warriors. Various other sculptures in relief, colossal statues, small clay vases, well-cast brass bells, &c. have been found in different places; and it is supposed, that upon due research being made, many more might be procured. But the principal and most prominent Mexican antiquities are the remains of the teocallis, or houses of the gods. These edifices were generally of a pyramidal form, rising, not by steps, but by a succession of four or five lofty terraces. On the summit were erected the temples, which served also as watch-towers, and in which were placed the colossal idols of the divinity, to whom the teocalli was consecrated; and to this platform a grand staircase on the outside afforded access.

The burial places of the kings and nobles were constructed within these pyramids, and around them were the dwelling places of the priests, with gardens and fountains enclosed by walls. These structures were frequently used as arsenals and fortifications, and are considered as bearing a striking resemblance to the Babylonian temple of Belus. The most remarkable of these edifices still existing are those of Teotihuacan, Papantla, and Cholula. The first are situated in the valley of Mexico, about eight leagues north-east from the capital, in a plain called the *path of the dead*, where there are two large teocallis, surrounded by several hundreds of smaller ones, forming streets in straight lines from north to south, and from east to west. Each side of the base of the largest measures 682 feet, and the perpendicular height 180 feet. The smaller pyramids are not above 30 feet in perpendicular height, and are supposed to be the tombs of the chiefs. The pyramid of Papantla, which was discovered only about the year 1780, by some Spanish hunters, is more tapering than any other monument of the kind, being only about 80 feet broad at the base, and about 65 in perpendicular height. It is built entirely with hewn stones of an extraordinary size, and regular shape; and has three staircases leading to the top. It is covered with hieroglyphical sculptures, and small niches to the number of 318 cut in its sides, and arranged with great symmetry. But the greatest and most ancient and most celebrated of these pyramidal structures, is the teocalli of Cholula, which, at a distance, has the appearance of a natural hill covered with vegetation. Its perpendicular height is 164 feet, and each side of its base 1440 feet. It is built of unbaked bricks, with alternate layers of clay; and on the platform is now erected a Catholic chapel, in place of the ancient temple of *the god of the air*. A few years ago a road from Puebla to Mexico was carried through the first terrace, which laid open a square room in the interior, built of bricks, and supported by cypress beams. The bricks were stepped over each other, the upper overreaching the lower, so as to meet in a point, and form a kind of Gothic arch, a mode of structure not uncommon in Egypt and India. This apartment had no outlet, but contained two human skeletons, several idols in basalt, and a number of curiously varnished and painted vases.

The history of the conquest of Mexico by the Spaniards has been already brought down, in the article Cortes, to the capture of Guatimozin, after the fall of his capital, in 1521. This memorable siege, which decided the fate of the Mexican empire, continued for the space of seventy-five days, with scarcely any interruption to the exertions of the assailants and defenders; and without the aid of the other Indian powers, all the superiority of the Spanish arms and discipline would not have been able to carry the place over the great abilities of Guatimozin, the number of his troops, and the peculiar situation of his capital. The exultation of the Spaniards in accomplishing this arduous enterprise was quickly damped by the inconsiderable amount of the spoil which they were able to collect amidst the ruins of the metropolis. Guatimozin, aware of his approaching fate, had ordered the remaining treasures in his possession to be thrown into the lake; and the Indian auxiliaries, while the Spaniards were engaged with the enemy, had carried off the most valuable part of the booty. To appease the discontent of the troops, and in compliance with their suspicions, Cortes was at length persuaded to subject the unhappy monarch and his chief favourite to torture, in order to force from them a discovery of the royal treasures, which they were supposed to have concealed. The prince resisted with invincible fortitude all the cruelty of his tormentors, but his fellow-sufferer expired under the violence of the anguish; and Cortes, at length ashamed of such barbarous proceedings, rescued the royal victim from the hands of his persecutors. The provinces of Mexico, after the fall of the capital, submitted to the conquerors without farther resistance; and small detachments of Spaniards marched without interruption in different directions to the shores of the Great Southern Ocean.

Even before any legal authority could be transmitted from the Spanish court, Cortes proceeded to exercise all the powers of a viceroy; and endeavoured, by various arrangements, to secure and improve the conquest which he had achieved. Having determined to establish the seat of government in its ancient station, he began to rebuild the ruined capital on a more extensive and magnificent plan. He employed skilful persons to search for mines, and encouraged his principal officers, by large grants of land and other privileges, to settle in the remote provinces. The natives, at times rendered desperate by their oppressions, ran to arms for the recovery of their liberties, but were uniformly overpowered by European discipline and valour. These efforts to regain their independence only served to aggravate their sufferings; and after every insurrection (which the Spaniards affected to consider as rebellion against a lawful sovereign,) the leaders were put to death by the most excruciating torments, while the common people were reduced to the state of personal servitude. In the country of Panuco, sixty caciques and 400 nobles were burnt at one time; and the families and relatives of the wretched victims were compelled to be spectators of their dying agonies. The captive prince Guatimozin, upon a slight suspicion of having devised a plot for shaking off the yoke, was ordered, without even the formality of a trial, together with two of the most distinguished chiefs of the empire, to be publicly hanged; and these acts of barbarity, coolly committed by Cortes and Sandoral, were readily imitated by persons of subordinate ranks in the perpetration of still greater excesses. The miserable Indians were every where dragged away to search in the rivers and torrents for the precious metals; but it does not appear that their avaricious oppressors profited greatly by their labours, and the early historians of America abound with accounts of the hardships and poverty of its conquerors. It was not till thirty years after the conquest, that the richer mines of New Spain were discovered; and that, under a more orderly government, more gainful researches were prosecuted.

Besides being dragged from their homes to labour in the mines, a great number of Indians were obliged to follow the armies, and to carry burdens above their strength, without sufficient nourishment or repose. In Mexico particularly, where a powerful and martial people made a more prolonged resistance to the invader, great multitudes fell in the field of battle. The introduction also of the small-pox, a disease unknown in the country, proved extremely fatal to the natives. By all these causes combined, the original inhabitants were rapidly diminishing in number. Numerous regulations were enacted by the Spanish government to protect the native Americans from the oppression of the European settlers; but all were ineffectual to restrain these rapacious and daring adventurers, when removed to so great a distance from the seat of authority. The Spanish ecclesiastics and missionaries exerted themselves incessantly for the protection of the natives, and are still considered by the Indians as their natural guardians, to whom they owe the various regulations enacted in their favour, and to whom they have recourse under every hardship to which they are subjected. One of the principal regulations intended for the protection of the Indians, but perverted to the very opposite purpose, was the system of *encomiendas*, by which the remains of the conquered race, instead of being left to be seized as slaves indiscriminately, were parcelled out in tribes of several hundreds of families, as grants to certain individuals as their protectors and proprietors. They were thus attached to the soil, and their work became the property of their masters, whose names they frequently assumed. But the evil thus only became worse, and more systematic; and it was not till the 18th century that the situation of the natives began to be ameliorated. As the families of these original proprietors became extinct, the encomiendas, being considered as fiefs, were not renewed. The viceroys, and particularly the audencias, watched over the interests of the Indians; and, in some provinces, their liberty and comfort have been gradually augmenting. Charles III. particularly, became their great benefactor, by annulling the encomiendas, and prohibiting the practices of the Corregidors, who were accustomed to supply the Indians with various articles at extravagant prices, so as to make them little better than slaves, by making them their debtors. But the establishment of intendancies, during the ministry of the Count de Galvez, in the beginning of this century, was the most memorable event in the history of Indian prosperity in New Spain, and, under the active superintendance of the intendants, the native race have begun to enjoy advantages and securities, of which they were deprived by the tyranny of the subaltern Spanish and Indian magistrates.

When the Mexicans had been brought to bear patiently the yoke of their conquerors, and the colonists had become tranquil possessors of all the treasures of the country, the warlike spirit insensibly declined, and the kingdom of New Spain, with the other settlements, enjoyed a peace of two centuries and a half. The internal tranquillity of Mexico has been rarely disturbed since the year 1596, when the dominion of the Spaniards was established over all the territories, from the peninsula of Yucatan and the gulph of Tehuantepec, to the sources of the Rio del Norte and the coast of New California. Disturbances among the Indians took place in 1601, 1609, 1624, 1692; and, in the last of these commotions, the palace of the viceroy, and some other public buildings, were burned by the insurgents. These disturbances, however, were occasioned chiefly by a deficiency of provision; and, as long as the native creoles were so few in number as to continue united with the European Spaniards, no spirit of independence appeared in the country. The first symptoms of such a spirit arose about the middle of the seventeenth century, after the commotions in New England; and, a few years before the peace of Versailles, the serious insurrection of Tupac Amaru, in Peru, alarmed the Court of Madrid with the apprehension of political commotions among the colonies; but it is only since the last thirty years that the colonists, having been brought, by greater freedom of trade, into contact with the United States, the British, French, and Danes, the political events in Europe, since 1789, have excited an interest among the Spanish creoles, and led them to aspire after their own rights as a people. The measures employed by the public authorities to quiet these agitations, particularly the prohibition of printing presses, even in towns of 40,000 or 50,000 inhabitants, and the proscribing of such works as those of Robertson, Montesquieu, &c.; the infliction of torture on several persons in New Grenada, suspected of revolutionary plans, and other similar instances of distrustful policy, served only to increase the discontents of the colonists. Nothing was done to forward their just demands, to improve the obvious defective institutions of the country, and to reform the most glaring evils of the colonial system; and in 1796, a great revolutionary commotion broke out in the province of Venezuela, which had nearly annihilated, in that quarter, the Spanish authority. The individual liberty which the colonists naturally enjoy, by their diffusion over a vast extent of country, and the mutual hatred of the different casts, especially the dread entertained of the blacks and Indians by the whole body of the whites, have prevented the popular discontents from spreading more generally in the other provinces. The events, particularly, which took place in S^t. Domingo, have contributed greatly to preserve tranquillity in the Spanish colonies on the continent. That tranquillity, however, has at length suffered an almost universal interruption, and insurrection has for several years, prevailed in every quarter of Spanish America. The progress of these revolutionary movements is still involved in too much uncertainty to afford any materials for a detailed account in this place, and would indeed far exceed the limits of the present article. There is less known, in this respect, of the events which have taken place in Mexico, than of any other Spanish settlement. Its secluded situation, the nature of its coasts, and its want of sea-ports, prevent any information from being received from the interior, except what the Spanish authorities may communicate. According to their accounts, all disturbances ceased in 1807; but various circumstances, particularly an intercepted letter from the Bishop of Valladolid, afford reason to believe that the country is full of insurgents, and that they are daily becoming better provided with the means of resistance. See Robertson's *History of America*, and Humboldt's *Political Essay on New Spain*. (*q*.)

MEZZOTINTO, is a kind of engraving which resembles drawing in China ink. Instead of the tedious and laborious operations of the graver, in highly finished plates, it is executed by a more simple and expeditious process in the following manner: The plate, with a piece of flannel under it, is to be laid on the table, and the grounding tool held perpendicularly in the hand.* While leaning moderately on it, the hand must be kept rocking in a right line from end to end, until the plate be wholly covered in one direction. Next let the strokes be crossed from side to side, and afterwards from corner to corner, working the tool each time over the whole plate in every direction, somewhat like the points of a compass; at the same time taking all possible care not to cut in one direction twice in a place. Thus the surface is covered completely with lines, and would produce a black impression if printed. Next, the designed effect is to be given by removing such parts of the surface as are necessary for light or sunshine. After the ground has been laid, the scrapings of black chalk are to be rubbed over the plate with a rag, or it may be smoked with candles. The drawing to be engraved is now to be traced on the plate, after having rubbed the black with red chalk dust. The lights and shades are to be produced by marking the outlines with a blunt needle, and scraping off the lights in every part of the plate as clean and smooth as possible, in proportion to the strength of the lights in the drawing, observing to preserve the outlines. Then the extreme light parts, such as the tip of the nose, the forehead, or lines, are to be softened or rubbed down with the burnisher. When an impression from the plate is dry, it should be touched with white chalk, where it ought to be light, and with black where darker; and the plate being retouched, the same course must be followed for the lights; and employing a small grounding tool for bringing the shades to a proper consistence. It is necessary to take successive proofs until the requisite quality be obtained.

By another method, the outlines of the object to be represented are etched, as also the folds in drapery, making the breadth of the shadows by dots, which must be bit to a proper depth by aquafortis. The ground used in etching is taken off, and the mezzotinto ground being laid, the scraping proceeds as before. Imison, *Elements of Science and Art*, vol. ii. p. 360.

Instead of following the manual operations of laying the ground of a mezzotinto engraving, Mr. Dossie has suggested that it may be attained with greater ease and accuracy by some mechanical means, and recommends the invention of a machine for that purpose. Vol. ii. p. 174. In his work are copiously detailed the whole process of engraving in mezzotinto, its uses and effects. It is there remarked, that "the principles on which the fitness or unfitness of subjects of this kind of engraving are founded, are of two kinds; the one respecting light and shade, the other the nature of the design with regard to the outline. Such pieces as contain large and clear masses of light do not succeed at all; but where, on the contrary, there is a large proportion of very dark parts, as in the representation of night scenes, or a large proportion of brown shades, as in the pictures of Rembrandt, Benedette, and Teniers, in some instances the best effect is produced, and with the least labour. Such pieces likewise as are of a simple composition, and do not require great force and variety of expression in passion and character, are suitable. But where great spirit is required to give merit, this manner of engraving fails, as it does not admit of those sharp and delicate strokes and touches which are the means of that expression." It thence appears, that mezzotinto engraving is best adapted to objects of considerable size. Nevertheless, some persons, such as Mr. Gilpin, incline to bestow greater qualities on it than it seems to deserve. It appears, indeed, that artists in general are disposed to elevate engraving to a higher rank than belongs to it. They wish it to be considered an original, not an imitative art. But what more is the most refined painting than mere imitation? It is either the description of real, or the representation of imaginary subjects. Engraving apparently holds a second place.

Facility of execution has been one principal means of diffusing mezzotinto engravings, while novelty has proved their recommendation. It appears, however, that what is susceptible of the greatest delicacy must be viewed as the most perfect. Mezzotinto has been more successfully cultivated in England than elsewhere, whence it is called on the continent the black or *English style*.

Evelyn ascribes the invention of this manner of engraving to Prince Rupert, Count Palatine of the Rhine, by whom he was acquainted with the method of executing it. But what he says is given under an air of great mystery, and he declines publishing the process, though expressing himself willing, privately and with permission of the Prince, to impart it to any "curious and worthy person." The author was at the same time furnished with the plate of a head engraved by the Prince, which is inserted in his work, *Sculptura, or the History and Art of Chalcography*. Chap. vi. Baron Heineken, however, refuses him this credit; and indeed both he and a later author, Huber, bestow it on Louis de Siegen, or de Sichem, a lieutenant-colonel in the service of the Landgrave of Hesse Cassel, who produced a mezzotinto print of the Princess Amelia, in folio, in 1643. Prince Rupert, having learned the method from him, imparted it to Wallerant Vaillant, a Flemish painter and engraver, on a promise of secrecy. But it was soon disclosed by the indiscretion of one of the workmen employed in preparing the copper. The engraving by Siegen is some years anterior to the date of Evelyn's publication. See Heineken, *Idée Générale d'un Collection des Estampes*, p. 208, Note. Huber, *Notice Generale des Graveurs*, p. 59. (*c*.)

MICHAELIS, John David, a celebrated German theologian and biblical critic, was born at Halle, in Lower Saxony, on the 27th of February, 1717. He received the rudiments of his education at the school of

* The *grounding tool* is like a steel chisel, the edge of which has a semicircular form, and is cut into very fine teeth. It is fixed into a wooden handle.

the Orphan House, and was chiefly indebted for his instruction in classical literature to his father, Christian Benedict Michaelis, professor of theology and the oriental languages in the university of Halle. He took his degree of master in the philosophical faculty at the university above mentioned, in the year 1739. In 1741, he made an excursion through Holland and England, and formed an acquaintance with those eminent orientalists, Schultens and Lowth. During his residence in England, the Bodleian library at Oxford presented a rich field for his indefatigable researches. After an absence of fifteen months he returned to Halle, where he delivered lectures on the historical books of the Old Testament. In 1745, he repaired to Göttingen, under the patronage of M. de Munchausen, where he continued his lectures, and was first appointed an extraordinary, and, in 1750, an ordinary professor in the philosophical faculty in that university. Here he had an opportunity of cultivating his talents, and extending his knowledge by assiduous study, and by a constant intercourse with Haller, Gesner, Mosheim, and other eminent scholars. He also obtained the situation of secretary to the Royal Society of Göttingen, of which he became director in 1761; and he was soon afterwards created an aulic counsellor by the court of Hanover. As his reputation increased, he was admitted, as an honorary or corresponding member, into various learned bodies in foreign countries.

The talents of Michaelis were no less usefully employed in the composition of various learned works, than in the zealous performance of his duties as a public teacher in the university. His critical researches into the scriptures of the Old and New Testament merit particular notice. When we consider the small aid he could derive from the labours of his predecessors, his illustrations of the Old Testament may be viewed as an almost entirely original work; and his introduction to the scriptures of the New Testament, although less valuable, perhaps, in a philological point of view, is still esteemed, in its last amended form, as an indispensible repertory of critical learning for every student of theology. His translation of the Bible, which was undertaken at the suggestion of Lessing, is chiefly valuable on account of the notes. His *Compendium Theologiæ Dogmaticæ*, which excited little sensation in Germany, was confiscated in Sweden; but Count Höpken, some years afterwards, endeavoured to repair the injury thus done to the learned author, by prevailing upon the king of Sweden to confer upon him the order of the Polar Star. The extensive knowledge which he had acquired in biblical philology, as well as in every department of learning connected with the study of the Scriptures, enabled him to form very accurate notions on the subject of the original and peculiar civil institutions of the Hebrews, which he published to the world in his treatise on the Mosaic law; a work which affords equal instruction and entertainment to the statesman, the historian, and the antiquary.

During a period of forty-five years, Michaelis continued to discharge his duties as a professor in the university of Göttingen with distinguished success and increasing reputation, by delivering lectures on various parts of the sacred writings, and communicating instruction in the Hebrew, Arabic, and Syriac languages. Towards the close of his life additional honours were conferred upon him. He was elevated, in 1786, to the rank of a privy counsellor of justice by the court of Hanover; and, in 1788, he was unanimously elected a fellow of the Royal Society of London. His laborious and useful life was terminated on the 22d of August, 1791, in the 75th year of his age.

We have already alluded to several of the works of Michaelis; and our readers will find a list of his various writings, which bear honourable testimony to his great learning and industry, in the *Gentleman's Magazine* for March 1792. A translation into English of his *Dissertation on the Influence of Opinions on Language*, was published in this country in 1772: and his *Introduction to the New Testament* was translated by Dr. Marsh, now Bishop of Llandaff, and published with Notes, &c. in 4 vols. 8vo. London, 1802.

MICHIGAN Lake, a large lake in the United States of America, is situated between 42° and 46° of North Latitude. It is of an oval form, about 260 miles long from north to south, about 945 in circuit, and has an area of nearly 10,368,000 acres. It runs into Lake Huron, and it is said to be unfathomable. The banks of the lake are thinly covered with pine, cedar, and shrub oak. It abounds with excellent fish, and trouts are sometimes found which weigh from 60 to 90 lbs. It is navigable for vessels of 400 tons. Lake Michigan is separated by a barren tongue of land from Lake Superior. See Morse's *Geography*, p. 63, and Warden's *Account of the United States*, vol. i. p. 71.

MICHIGAN TERRITORY.

Situation and *Boundaries*. The states of Indiana and Ohio, south; lake Michigan, west and north west; the Straits of Michilimakinac, north; lake Huron, north-east; and the river St Clair, lake St. Clair, Detroit river, and lake Erie, east. The southern extremity of Michigan is in N. Lat. 41° 37′, and its northern in N. Lat. 45° 41′.

Extent and *area*. Its greatest length from north to south, is, from Fort Michilimakinac to the N. W. angle of the state of Ohio, 286 miles; its greatest breadth from east to west, is. from the mouth of St. Clair river, to lake Michigan, 174 miles. From its irregular form, it is difficult to estimate with precision, the area in square miles of the peninsula of Michigan, but, approximating by the rhumbs, 34,600 will not differ more than a very small fraction from its real superficies. This is equal to 22,144,000 English, or U. S. statute acres. This extent exceeds considerably, the estimates formerly made in our common geographical works; but arises from now placing lake Michigan in its true position, nearly S. W. and N. E; this lake, until found otherwise by recent and more accurate observation, was considered as extending north and south, and was consequently erroneously delineated on most maps upon which it was placed, and of course the peninsula too much contracted.

Features. The peninsula of Michigan is an extensive table land, resting upon a vast stratum of secondary rock, composed of limestone and argillaceous sandstone. This structure imposes a peculiar physiognomy upon the country. The interior towards the sources of the rivers, is generally level and interspersed with lakes and morasses. The rivers, near their sources, are sluggish in their courses; deep and muddy beds give them a monotonous and disagreeable appearance; these characteristics vanish as the streams advance towards their respective places of deposit, from the following cause. A narrow border, or inclined plane of about 20 miles width, skirts the whole territory, from its south-east angle on lake Erie, to its south-west on lake Michigan. As the rivers approach this declivity, their currents become more rapid, and in most instances fall over precipices of secondary rock, and again become sluggish a few miles before entering their final deposit. Along the entire extent of this plain, the lands are fertile, generally rolling, well wooded, and extremely well adapted to agriculture. Its length being near 700 miles, and breadth averaging 20 miles, yields an area of 14,000 square miles, or nearly 9,000,000 of acres. In the interior, particularly towards the N. W. part of the peninsula, prairies, (*natural meadows*,) are common and extensive. Marshes, in many places, border the mouths of the rivers, but do not extend far inland. But though lakes, prairies, marshes, and cultivated fields occur, and diversify the aspect of the country, they are collectively limited in extent; more than seven-eighths of the whole peninsula is yet covered with a dense forest.

Lakes, *Bays*, *Islands*, and *Rivers*. In marking the boundaries, we have noticed the large lakes of Michigan, Huron, St. Clair, and Erie, which respectively serve as part of the limits of the peninsula of Michigan (*which articles see.*) In the interior, a very great number of small lakes exist, but not individually of sufficient importance to merit particular notice. Maumee bay, formed by the mouth of Maumee river, is about 8 miles long and 3 wide, with 7 feet water on the bars. A small island in form of a crescent, three-fourths of a mile long and about 100 yards wide, lies in the mouth of this bay, consequently it has two channels of entrance. The N. W. part of lake St. Clair, has received the name of Anchor bay, but possesses no particular feature deserving notice.

Saguina bay is the most remarkable of all those which indent Michigan. This is an immense opening from lake Huron, of upwards of 70 miles in length, and gradually narrowing from 35 miles in width, to a small river of the same name, whose sources are on the interior table land; the general range of Saguina bay is from N. E. to S. W. bordered by excellent land.

Traverse bay extends itself from lake Michigan, at N. lat. 45° 10′, and penetrates the country in nearly a south direction about 40 miles, where it contracts into a river of the same name. It is very remarkable that the eastern shore of lake Michigan, from the mouth of Traverse bay to that of Calumet river, at its southern extremity, is without bays, and presents the most dangerous navigation of a similar extent in all the Canadian sea.

In the S. W. part of lake Erie, a number of small islands exist, all of which have received distinctive appellations. Though these islands are not yet definitely assigned to any particular territorial section, yet from their proximity to Michigan, we have deemed it correct to enumerate them in the recapitulation of the natural features belonging to that country. Bass Islands is a group containing three larger and four smaller islands; the three larger Bass islands, lie nearly north and south of each other, and are about two miles long and half a mile wide each. In the southern Bass island, on its northern side, is the fine and commodious harbour of Put-in-bay, six miles west of which, on Sept. 10th, 1813, the British fleet, under Commodore Barclay, was defeated and captured by Commodore Perry. The Hen and Chickens, are four very small islands lying near each other, six or seven miles N. W. of the Bass Islands. The Hen and Chickens are unimportant, except as land marks in navigating lake Erie. The west, middle, and eastern Sisters, are three islands which, though designated as relatively north and south of each other, in fact range in nearly a S. W. and N E. direction; they are all small, neither exceeding 15 or 20 acres in extent, are well wooded, and about ten miles apart, and serve as excellent land marks to navigators on the circumjacent parts of the lake. The eastern, or rather north-eastern Sister, is fifteen miles S. E. from the mouth of Detroit river.

Celeron, Gros Isle, Bois Blanc, Grand, (*large*) and Petite, (*small*) Turkey Islands, Hog, and Peach Islands, all lie in Detroit river. Gros Isle, and the larger Turkey island, contain considerable bodies of good soil, upon which are several farms Bois Blanc deserves notice, only from its position, lying opposite Fort Malden, or rather the village of Amherstberg in Upper Canada, and having the main, and indeed the only ship channel (not more than 300 yards wide) into Detroit river, between it and the Canadian shore; its possessors must command the ingress and egress of the navigation of that important pass. The other islands in Detroit river are undeserving of particular notice. The river St. Clair, at its entrance into the lake of the same name, divides into a number of channels, forming intermediate islands; but being generally low, flat, and marshy, are of no consequence in a geographical point of view.

Michilimakinac is a small, but very important island, lying in the Strait between lakes Huron and Michigan. The United States have a fort and factory upon this island. There are a number of other islands in the Strait between lakes Huron and Michigan, and contiguous to Michigan, in each of those lakes, along their respective shores, but are uninhabited and unimportant.

The rivers of Michigan are numerous, and, compared with their length, of course, of large volume. The most remarkable of those which flow from the interior, are, Maumee, Raisin, Huron of Erie, Riviere aux Ecorces, Riviere Rouge, Huron of lake St. Clair, Belle riviere, Pine river, Saguina, Grand, Traverse, Marguerite, Mastigon, Grand Maremec, and St Joseph's rivers. Before, however, noticing the streams flowing from the interior, Detroit, and St. Clair rivers, and the Strait of Michilimakinac demand previous attention. The immense mass of waters pouring into lake Michigan, so much more than counterbalance the diurnal evaporation from its surface, that a strong and perpetual current passes from Michigan into Huron, through the Straits of Michilimakinac. The body of water in lake Huron, augmented by the overwhelming discharge from lakes Superior and Michigan, together with its own particular smaller confluents, gradually contract into St. Clair river, passes Fort Gratiot, by a strong rapid, which gradually subsides into a placid stream, flowing nearly south, about three-fourths of a mile wide, and twenty-six miles in length. It is a singular feature in the topography of the country under review, that St. Clair river assumes, at its point of discharge, all the peculiar features of the Deltas, of the Nile and Mississippi rivers. Detroit river commences at the S. W. angle of lake St. Clair, and running six miles and a half nearly in a west direction, passes the city of Detroit, by a channel of three-fourths of a mile wide. Opposite the city of Detroit, the river is narrower than it is in any other part of its course. Below the city, the river winds three and a half miles S. W. to the mouth of the Riviere Rouge (*Red River*,) thence turning to the south, gradually widens, and in a distance of eighteen miles from the mouth of Riviere Rouge, to that of Huron of Erie, expands to five miles in breadth at its junction with lake Erie. Vessels drawing seven feet water, pass without difficulty from lake Erie, through the intermediate straits and lakes, into Huron and Michigan, and towards lake Superior as far as the falls of St. Mary.

Of the rivers we have enumerated as flowing from the interior table land, only those upon whose banks civilized settlements have been made, are adequately known, or deserve notice in a brief review. Maumee river rises in the states of Ohio and Indiana, has only its discharge in the territory of Michigan; it is of importance in the topography of the latter, as forming its S. E. commercial entrance. Riviere Raisin (*Grape river*) rises in the interior uncultivated wilds; is about 150 miles in length, including windings, and for fifty miles above its mouth about 90 yards wide. Six miles above its mouth, it is precipitated over rapids or rather falls. A bar at its mouth prevents the entrance of vessels drawing more than two feet water. The lands on this river are of very excellent quality; timber, oaks of several species, sugar maple, linden, yellow wood, (*Liriodendron tulipifera*,) hickory, ash, and many other trees. Settlements are extensive, and farms well cultivated, near the mouth of the Raisin; this river falls into lake Erie, thirty-five miles from the city of Detroit. Huron of Erie is one of the largest and longest streams which rise on the table land of Michigan. This river has many confluent branches which interlock with those of Grand river flowing into lake Michigan. The Huron, including its windings, exceeds two hundred miles in length; its breadth, seventy or eighty miles above its mouth, 80 or 90 yards. Its shores are extremely fertile, producing nearly similar timber trees with those of the Riviere Raisin. It may indeed be observed, in order to avoid repetition, that the forest trees which enrich and adorn the borders of the rivers and lakes of Michigan, are generally of similar genera and species. Huron of Erie enters the latter, at the mouth of Detroit river; admits vessels of four feet draught four miles to its fifth rapid. Both banks are settled for twenty or twenty-five miles above its mouth; soil productive; surface hilly, or rather rolling, on its S. W. side; more level and sandy on that of the N. E. Riviere aux Ecorces (*Bark river*) is in reality only a creek, not more than 20 miles in its entire length, entering Detroit river opposite Grand Turkey island, three miles below the mouth of the river Rouge; but gains importance from the excellence of the land it waters, and the extensive farms which chequer the shores of all its branches. This small stream contains one of the most wealthy and compact settlements yet made in Michigan Territory. Riviere Rouge (*Red river*) rises about twenty-five miles in a direct line, nearly north from the city of Detroit, curves to the south-west, south and south-east, falls into Detroit river three and a half miles below the city of Detroit. The entire length of this small river, including all its windings, does not amount to fifty miles; its breadth, in no part of its course, more than 45 yards. The soil it drains is, however, a compensation for the brevity of its volume. More than one half of all the civilized inhabitants of Michigan, exclusive of those in the city of Detroit, are found upon the banks of the Riviere Rouge, and those of its branches. From the peculiar course of this river, being upon the inclined plane, sloping from the interior towards Detroit river; its banks are every where sufficiently dry and elevated for cultivation.* Huron of St. Clair rises on the interior table land, is a stream of magnitude, but little, if any, inferior to that of Huron of Erie. Huron of St Clair has interlocking branches with Riviere Rouge, Huron of Erie, Grand river, and the streams which flow north into lake Huron, and Saguina Bay. The settlements yet made on this river, are near its mouth, though the soil it waters yields, in no respect, to any part of the Michigan peninsula; it is navigable for vessels drawing three feet water twelve miles, where rapids occur. New settlements are extending along this river, and a new town, Mount Clemens, laid out (1818) five miles above its mouth, on its northern bank. Saline and Swan rivers enter Anchor Bay N. E. of the mouth of Huron river; Belle riviere, Pine river, and river Delude, fall into St. Clair river. None of these latter streams are of sufficient importance to merit particular description; upon all, settlements are formed, and the soil productive.

It would be useless to swell this article, by detail on the other rivers of Michigan, whose shores are yet wilderness, and whose courses, sources, and length, are of course but imperfectly known; we therefore only mark their names, and leave their description to a period of future geographical discovery.

Soil and *productions*, *vegetable* and *mineral*; *seasons* and *climate*. We have already observed, in our notice of its rivers, that the soil of Michigan was generally fertile; we may here repeat, that except where rendered otherwise by marshes, or flats too level to enable nature to drain the water accumulated by rain, that the soil of Michigan is, in a high degree, adapted to all the purposes of agriculture. If one half the area of the peninsula is deducted as unproductive, and this is certainly too large an allowance, yet 17,300 square miles, or 11,072,000 acres remain capable of cultivation. It ought to be carefully noted also, that most of that part of the surface which is really too low and wet for culture is thickly wooded, therefore completely subservient to the various purposes of human enjoyment and convenience, where wood is demanded. It may also be observed, that Michigan exceeds in extent New Hampshire, Vermont, Massachusetts, Connecticut, and Rhode Island taken together; lies in a similar climate, and certainly, in comparative extent, contains more productive soil than exists on all the combined area of the latter

* The United States have a ship yard, four miles up this river, to where vessels drawing 16 feet water can ascend; a peculiarity which distinguishes it from all the other rivers of Michigan, whose sources are in its interior; not one of which yet explored, affords half the depth. Vessels drawing three feet, ascend the river Rouge eight miles above the ship yard.

states. By the census of 1810, those states possessed a population of nearly 1,243,000 persons, upon a surface of 31.200 square miles; therefore, if the peninsula of Michigan was peopled only equal to those less productive states, or about 40 inhabitants to the square mile, it would contain 1,384,000 souls. This estimate may, and no doubt will, excite surprise, but we are convinced falls short of the real capability of that too little known, but really fine region.

It would swell this article much beyond its due extent, to enumerate the various natural productions of Michigan. Of minerals or fossils, the nature of the country precludes much variety. Carbonate of lime is the most important, and indeed the only extensive mineral production yet discovered; this rock is found to underlay the Bass Islands, and many other parts of the country.

Of timber trees, perhaps no section of the United States possesses a more extensive and richer variety. Three or four species of oak; as many of hickory and walnut; ash, linden (*tilia*), sugar maple, red maple, elm, and white poplar (*liriodendron tulipifera*), may be enumerated as the principal species. Underwood and vines are numerous, and in many places render the extensive forests almost impervious. This circumstance alone attests strongly the natural fertility of the soil.

The native grasses in the praries and marshes are of various species, and are succulent and excellent for pasturage. The most valuable vegetable production of Michigan, and perhaps of all the northern parts of this continent, is the fols avoine, *zizania aquatica*. This elegant grass has received a misnomer from the pedantic repetition of European names. In fact, it specifically differs as much from oats or rice, as do the latter from each other, and can be compared with either, only as having a panicle as its mode of inflorescence. The Fols avoine covers the marshes near the margin of the lakes and rivers, and no other gramina, not even wheat, has so fine and beautiful an appearance when in bloom or ripe. Its grain is elongated, full, sweet, and nutritious. In a future density of population, the importance will appear of a cereal gramina, vegetating spontaneously where no other useful vegetable can, without the utmost exertion of human labour, be made to exist. The extent of North America, where this excellent native grain is found, almost exceeds belief. From Louisiana to the Arctic circle, it exists upon the streams and lakes, in a greater or less quantity; but the Canadian sea about N. Lat. 45, appears to be its most favourite residence.

Of exotic vegetables introduced into Michigan, all have succeeded which were suitable to the climate. Wheat, rye, oats, barley, flax, hemp, garden vegetables, and meadow grasses flourish. Neither farming, gardening, or the management of meadows and orchards, are pursued with even tolerable skill by the inhabitants; the beneficence of nature has to supply what is left undone by human ignorance and improvidence. Fruit, such as peaches, apples, cherries, and plums, are plentiful and delicious, maugre defective husbandry. In brief, the rude essay already made, amply demonstrates that population, science, and industry are only wanting to render Michigan one of the most flourishing and desirable sections of the United States.

A common observation is made, that the climate of Michigan is more mild than that of similar latitudes more to the eastward, towards the Atlantic coast. We are inclined to consider such an opinion founded upon erroneous principles. Lake Erie is only 565 feet above the Atlantic ocean, and no part of Michigan is perhaps 150 feet above the surface of Erie, or much more than 700 feet above the level of the Atlantic ocean; whilst much of the intermediate space is double that elevation, and consequently much more subject to the action of frost. The rivers and lakes of Michigan are, however, annually frozen; snows are heavy and lie long upon the earth, a circumstance in itself in a high degree salutary to fruit trees and small grain. The climate, in brief, differs in no essential respect from that in similar latitudes, elevation, and exposure. The summers are often oppressively warm, which, acting upon such extensive masses of fresh water as almost encircle the country, and cover much of its surface, exposes the inhabitants to intermittents, and other complaints in autumn. The climate is, nevertheless, in general salubrious, and the inhabitants healthy.

Animals. The land animals found native, were the elk, deer, bear, wolves, foxes, wild-cats, &c. Innumerable flocks of migratory water fowl, such as geese, ducks, swan, teal, and some others, cover the extensive marshes and ponds of Michigan at the approach of winter, in search of the fols avoine, and a milder climate. The same may be said of the wild pigeons, which often visit this country in countless thousands.

The fisheries in Erie, Huron, and Michigan lakes, compose a very important part of the domestic policy of the inhabitants of Michigan, as at once affording employment and subsistence to a large portion of their number. The fish usually caught are, the white fish, and salmon trout; both of exquisite flavour and taste. Many other species are however caught, of excellent quality.

Domestic animals, introduced into the country, are the same as found in every other section of the United States, and therefore need no particular mention.

Inhabitants, towns, government, counties, population, and *historical epochs.* The first civilized inhabitants of Michigan were Canadian French, from Montreal and elsewhere. A small trading post was formed at Detroit, long before the final conquest of Canada by the British, in 1759. After that event, the post at Detroit was continued by the conquerers. The original French remained, and their descendants multiplied, and now compose more than a moiety of the population of the territory. The residue is composed of a medley of emigrants from the United States, Canada, and Europe. The manners of the people are mild and affable. Education is neglected, and literary information confined to a few. The people who inhabit Michigan, are the most detached portion of the inhabitants of the United States; their external intercourse is very limited, which perhaps superinduces an indifference for those intellectual endowments which confer marked superiority on those who possess their advantages. Extended and approximating population will remove this, and many other evils, against which our frontier inhabitants have to contend.

The only town yet formed in Michigan worthy of particular description, is the city of Detroit, which is situated in Wayne county, and stands upon the right bank of the strait or river of the same name; N. Lat. 42° 15′ 36″—W. Long. from Washington City 5° 36′—or 82° 36′ W. from Greenwich. Detroit contains about 200 dwelling houses, and about 1200 inhabitants; a number of taverns and stores; one church, a court-house and jail, and an academy. The site of the city rises by a gentle acclivity from the river to the main street, and thenc extends backwards level, or very gently rolling. Being the *entrepot* between the United States and Canada, and the interminable Indian country in the interior of the continent, a military and naval post, and the seat of territorial government, more activity prevails at Detroit than could be expected from its remote and isolated position. It is in reality a thriving and prosperous town.

Munroe on the riviere Raisin in Munroe county, Browpstown above the mouth of Huron of Erie, and Maguaga in Wayne county, and Mount Clemens in Macomb county, have received the appellation of towns, though neither have assumed adequate importance to merit farther notice in this review.

The government of Michigan is that of the first grade of territorial administration. The governor and two judges adopt laws, and concentrate the legislative and highest juridical power in themselves. By a special act of congress, the territory has a delegate who sits in the house of representatives, with liberty of debate without power of voting. The ordinary minor subjects of judicial interference, are adjudged by courts of quarter sessions, composed of justices of the peace, who act in their individual capacity in the same manner as such officers act elsewhere in the United States.

The counties of Munroe, Wayne, and Macomb, embrace nearly all the settled parts of Michigan. The county of Munroe embraces the south-east parts of the territory as far as the river Huron of Erie; Wayne the region adjacent to the city of Detroit; and Macomb the extent along Lake St. Clair, and St. Clair river; each of those counties extend indefinitely westward. Some other counties have been named, such as Saguina, Michilimakinac, &c. but their extent and limits are too vague and precarious to merit farther notice.

By the census of 1810, the population of Michigan was made less than 5,000; this enumeration was, there is no doubt, much too confined; the territory, in August 1818, we are well assured, contained at least 10,000 persons, notwithstanding the very limited emigration in its favour, and the disasters of the last war between Great Britain and the United States, which fell with so much weight upon this section of country.

The historical epochs in which Michigan is particularly interested, are—Its original settlement by the French previous to 1760; occupation by the authorities of Great Britain to 1796; its occupation by the United States, separation from the N W. territory, and creation into a territory bearing the present title, 1802; General Hull's invasion of Canada, July 11th, 1812; battle of Brownstown, August 4th, 1812; evacuation of Canada, August 7th, 1812; battle of Maguaga, August 9th; and surrender of the city of Detroit, and territory of Michigan, to General Brock, August 16th, 1812; battle of Erie, and capture of the British fleet, September 10th, 1813; re-conquest of Michigan by the United States army under General Harrison, September 30th, 1813; battle of the Thames, and close of military operations in that quarter, October 5th, 1813; admission of a delegate from Michigan on the floor of Congress, at the session of 1819—20.

We may conclude this article by observing, that though the United States' posts at Green Bay and Prairie du Chien are, for civil purposes, put under the jurisdiction of the government of Michigan, we confined our notice to the peninsula, properly so called, as a connexion with those distant places is merely temporary, and must cease, when Michigan assumes her rank as a state of the United States.

DARBY.

MICKLE, WILLIAM JULIUS, celebrated as the translator of the Lusiad of Camoens, was born in 1734, at Langholm in Scotland, and was the son of the minister of the parish. After receiving a good education at the High School of Edinburgh, he went to London in 1763, and carried with him his poem "On Providence," which gained him the friendship of Lord Lyttleton. He was then employed as corrector of the Clarendon press at Oxford, and in 1767 he published his poem, called "The Concubine!"

His great work, the translation of the Lusiad, was printed in 1775, and contained an account of the Portuguese conquests in India, a life of Camoens, and a dissertation on the Lusiad. In 1779 he was appointed secretary to Governor Johnson, when he received the command of the Romney, and he was left at Lisbon as government agent for prizes. In that capital he was received with much attention as the translator of their great poet, and was admitted a member of the Royal Academy of Lisbon. Here he wrote his poem of "Almada Hill," an epistle from Lisbon. Having acquired some property, he returned to England, and settled at Whitby, near Oxford, where he died in the year 1769. His poems were published in 1794, in one volume, 4to.

MICROMETER.

THE word MICROMETER, from the Greek words μικρος, small, and μετρον, a measure, is the name given to an instrument for measuring small angular distances in the heavens, or small rectilineal spaces of any kind.

The micrometer was invented by our countryman, Mr. Gascoigne, about the year 1640-1, at which time he drew up an account of it in a letter to Mr. Oughtred. It consisted of two pieces of brass, ground to a very fine edge, and their edges were made to approach to or recede from each other, by a mechanical contrivance. Mr. Gascoigne had made use of it for several years in measuring the diameters of the moon and planets, in ascertaining distances at land, and in many nice astronomical observations. According to Mr. R. Townley, into whose hands one of these micrometers fell, a foot could be divided into 40,000 parts. Mr. Gascoigne had prepared a Treatise on optics for the press, but he was killed during the civil wars, in the service of Charles I. The MS. of this treatise was never found.

It appears from the Ephemerides of the Marquis of Malvasia, published in 1662, that he employed a net of silver wire in the focus of the eye-glass of his telescopes, for measuring the diameters of the planets, the distances of the fixed stars, and for taking an accurate drawing of the lunar spots. He had also a contrivance for turning this net in the focus of the telescope, in order to cause the star to move along one of his wires, and he obtained the angular distance of the wires, by counting the number of seconds which a star required to pass over one of the intervals of his net.

In the year 1666, Messrs. Auzout and Picard, without knowing any thing of the micrometer of Gascoigne, published the description of a micrometer, which consisted of silver wires, or fibres of silk, which were opened and shut by means of a screw.

The micrometer was soon pretty generally introduced among the instruments of an observatory, and underwent great improvements: New forms of it were invented; and by the successive labours of astronomers and opticians, it has been brought to a very high degree of perfection. These various improvements and new forms of the micrometer, will be described under the following nine chapters.

I. On fixed micrometers with an invariable scale.
II. On Wire-micrometers, in which the wires are opened and shut mechanically.
III. On Wire-micrometers, in which the wires are opened and shut optically.
IV. On Double image micrometers, in which the lenses or mirrors are opened and shut mechanically.
V. On Double image micrometers, in which the lenses, or mirrors, or prisms, are opened and shut optically.
VI. On Angular or Position micrometers.
VII. On Lucid disc micrometers.
VIII. On Doubly refracting micrometers.
IX. On Micrometers for microscopes.

Chap. I.—*On Fixed Micrometers with an Invariable Scale.*

The earliest micrometer of this description that appears to have been used by astronomers, was constructed by the celebrated Huygens. In the focus of the eye-glass of his telescope, he fixed a brass plate with a circular aperture a little less than that of the eye-glass. He measured the angle subtended by the diameter of this circle, by measuring the time of a star's passage over it, which he found to be $17\frac{1}{4}$ minutes. He then prepared two or three long and slender brass plates of various breadths, whose sides were very straight, and converged very gradually. In using these plates to measure the diameter of a planet, he slid one of them through two slits in the opposite sides of the tube, so that the plane of the long plates touched the plane of the circular aperture, or field; and he then observed in what part of the plate the breadth of it just covered the whole planet. By taking this breadth between the points of a pair of fine compasses, and by comparing it with the diameter of the aperture, he obtained the apparent diameter of the planet. Sir Isaac Newton has remarked, that the diameters of the planets are always somewhat bigger, when measured in this way, than they ought to be. This error, however, might have been corrected by using long tapering slits in place of plates.

A fixed micrometer, or *reticulum*, for determining the relative places of stars, was invented and used by M. Cassini. It consists of four hairs *a b*, *c d*, *e f*, *g h*, (Plate CCCLXXV. Fig. 1.) crossing one another at right angles in the focus of the eye-glass at the same point *i*, so that the two first are inclined 45° to the two last. The telescope is then directed, so that the preceding star may appear upon the hair *a b*, and is then turned about its axis till the star moves along *a b*. The time of the first star's arrival at the centre *i*, is then noted by a clock, and likewise the time of the subsequent star's arrival at the perpendicular hair *e d*. The interval between these times, converted into degrees and minutes, is the difference of the right ascensions of the two stars. In order to find the difference of their declinations, the times of the subsequent star's arrival at the points *k* and *l* of the oblique hairs *e f*, *g h*, is noted. The half of the interval between these times, is the time in which it describes *l m*, or *m k*, which, converted into degrees and minutes, gives the angular distance *l m*; and this being diminished, in the ratio of the radius to the cosine of the star's declination, gives the value of *m i*, the difference in declination of the two stars.

This reticulum was much improved by our eminent countryman, Dr. Bradley. In order to avoid the inconvenience of turning the telescope about its axis, he placed the ring *a b c*, (Plate CCCLXXV. Fig. 2.) of the reticulum, in a groove cut in the fixed ring ABC, and having confined it laterally by three small plates of brass at A, B, C, he gave it a motion round the axis of the tube by the endless screw DEF, working in a toothed arch *d e* fixed to the moveable ring *a b c*. The hairs *g h*, *i k* cross one another at right angles at *f*, the centre of the rings; and when the telescope is so placed that the range of a star falls upon *f*, let us suppose it to move in any line *f g*; then, by turning the nut D, and consequently the hair *f d* about the fixed point *f*, till it touches the star at *q*, it will then coincide with the direction of the star's motion, and then all other stars will move parallel to it. In order to find the difference of declination of two stars, he observes the times of their arrival at the edges of two slender brass bars *g i o*, *g k p* fixed to the ring *a b c*, and equally inclined to its diameter *g h*, at an angle of 26° 34′, when *f k* and *f i* will be each one half of *f g*, and *k i* = *f i*. Hence the difference of *i k* and *l n* will be equal to *f m*, the difference of their heights: that is, the difference of the times of the transits of the stars over any two bars *i k* and *l n* will be the difference of their declination as already explained.

A very simple and useful micrometer, invented by M. Cavallo, is represented in Plate CCCLXXV. Fig. 3. It consists of a thin and narrow slip of mother-of-pearl, finely divided into 200dth parts of an inch, by lines which reach from one edge to near the middle of the scale. It is about the 24th part of an inch broad, and its thickness is equal to that of common writing paper. The simplest way of fixing it, is to stick it by strong cement, on the diaphragm or field-bar, placed in the focus of the eye-glass next the eye. The micrometer which M. Cavallo adapted to a three feet achromatic telescope, magnifying about 84 times, had each of its divisions nearly equal to a minute, and as $\frac{1}{8}$th part of a division could be estimated by the eye, it was capable of measuring angles within $7\frac{1}{2}$ seconds of a degree. M. Cavallo determines the value of the divisions, by observing the space which any number of divisions subtends at a measurable distance, and computing trigonometrically the angle subtended by that space. It is preferable, however, in all cases, to ascertain the angular extent of the field of view by the time of the passage of an equatorial star, and to observe the number of divisions of the micrometer which correspond to that angle.

"This simple micrometer," says Dr. Brewster, "is very convenient in portable telescopes, where the eye-piece has a motion about its axis; but in telescopes supported upon stands, where the eye-piece is moved by a rack and pinion, the slip of mother-of-pearl cannot turn round upon its axis, and, consequently, can only measure angles in one direction. This difficulty, indeed, might be surmounted by a mechanical contrivance for turning the diaphragm about its centre, or, more simply, by giving a motion of rotation to the tube which contains the first and second eye-glasses. As such a change in the eye-piece, however, is often inconvenient and difficult to be made, Mr. Cavallo's micrometer has this great disadvantage, that it cannot be used in reflecting telescopes, or in any achromatic telescope where the adjustment of the eye-piece is effected by rack-work, unless the structure of these instruments is altered for the purpose. Another disadvantage of this micrometer arises from the slip of mother-of-pearl passing through the centre of the field. The picture in the focus of the eye-glass is broken into two parts, and the view is rendered still more unpleasant by the inequality of the segments into which the field is divided. In addition to these disadvantages, the different divisions of the micrometer are at unequal distances from the eye-glass which views them, and therefore can neither appear equally distinct, nor subtend equal angles at the eye."

In order to remedy these inconveniences, Dr. Brewster was led, in 1805, to contrive the circular mother-of-pearl micrometer, which is free of all these disadvantages, and has likewise the benefit of a kind of diagonal scale, increasing in accuracy with the angle to be measured. This micrometer, which he has often used, both in determining small angles in the heavens, and such as are subtended by terrestrial objects, is represented in Plate CCCLXXV. Fig. 4. which exhibits its appearance in the focus of the first eye-glass. The black ring, which forms part of the figure, is the diaphragm, and the remaining part is an annular portion of mother-of-pearl, having its interior circumference divided into 360 equal parts. The mother-of-pearl ring, which appears connected with the diaphragm, is completely separate from it, and is fixed at the end of a brass tube, which is made to move between the third eye-glass and the diaphragm, so that the divided circumference may be placed exactly in the focus of the glass next the eye. When the micrometer is thus fitted into the telescope, the angle subtended by the whole field of view, or by the diameter of the innermost circle of the micrometer, must be determined either by measuring a base, or by the passage of an equatorial star; and the angles subtended by any number of divisions or degrees will be found by a table constructed in the following manner.

Let A $m\,p\,n\,b$, Plate CCCLXXV. Fig. 5. be the interior circumference of the micrometer scale, and let $m\,n$ be the object to be measured. Bisect the arch $m\,n$ in p, and draw C m, C p, C n. The line C p will be at right angles to $m\,n$, and therefore $m\,n$ will be twice the sine of half the arch $m\,p\,n$. Consequently. A B : $m\,n$ = Rad : Sine of $\frac{1}{2}\,m\,p\,n$; therefore $m\,n \times$ R = sin. $\frac{1}{2}\,m\,p\,n \times$ AB, and $m\,p\,n = \frac{\sin\frac{1}{2}\,m\,p\,n}{R} \times$ AB; a formula by which the angle subtended by the chord of any number of degrees may be easily found. The first part of the formula, viz. $\frac{\sin.\frac{1}{2}\,m\,p\,n}{R}$, is constant, while AB varies with the size of the micrometer, and with the magnifying power which is applied. Dr. B. therefore computed the following Table, containing the value of the constant part of the formula for every degree or division of the scale.

Degrees.	Constant part of the Formula	Degrees.	Constant part.	Degrees.	Constant part.	Degrees.	Constant part.
1	.0087	46	.3907	91	.7133	136	.9272

A series of micrometers, principally for the purposes of microscopical observations, were constructed by the late Mr. Coventry of Southwark, with a degree of delicacy and accuracy which was never before equalled. They consisted of glass, ivory, and silver scales, on which are drawn parallel lines from the 10th to the 10,000dth part of an inch.

Mr. Barton of the mint, well known for his mechanical ingenuity, has carried the art of dividing micrometrical scales to the highest degree of perfection. The engine which he uses was given to him by his late father-in-law, the celebrated Mr. Harrison. It was constructed by Mr. Harrison himself, and its merits depend chiefly on the beauty and excellence of the screw; the apparatus for cutting which by an excellent inclined plane, also accompanied the engine The plate in the screw is not divided higher than 2000dth parts of an inch; but Mr Barton has drawn divisions on glass, so minute as the 10,000dth part of an inch. In drawing lines of 2000 in an inch, Mr. Barton often leaves out *one line* by design; and one of the greatest proofs of the stability of the engine is, that after having taken off the brass table with the work upon it, when the omission is distinctly perceived, *he can restore it to its place, and introduce the line without its being distinguishable from the rest.*

CHAP. II.

On Wire Micrometers, in which the Wires or Fibres are opened and shut mechanically.

In the original micrometer of Mr. Gascoigne, two metallic edges were made to separate from and approach one another; and when his instrument was shown to Dr. Hooke, he immediately suggested the substitution of fine wires in place of the edges of metallic plates, and they have accordingly been retained in almost all the subsequent forms of the instrument.

The wire micrometer, as constructed by Messrs. Auzout and Picard, underwent various improvements in the hands of Dr. Bradley and other astronomers, and in our article Astronomy, we have given a drawing and description of one of the most improved kind, as made by Mr. Troughton.

In all micrometers with moveable fibres, their separation and approach is effected by means of a screw with about 100 threads in an inch, and as every revolution of the screw is again divided upon a circular plate into 100dths of an inch, the 10,000dth part of an inch may be perceived in the number of the wires. Sometimes the screws are made with 200 or even 300 threads in an inch, with the view of giving additional delicacy to the scale, but in cases of this kind the threads are so minute, that they have not the requisite strength for a micrometer.

The double screw of Mr. Hunter, which we have already described in our article Mechanics, furnishes us with the means of obtaining a very slow motion in the moveable wires by means of two screws, with different numbers of threads in an inch, the effect being the same as if a single screw was employed, having the size of its threads equal to the difference of the size of the threads of the two screws.

The very same contrivance, with a slight modification, has been proposed by M. Prony, under the name of the *nonius screw*, for the purpose of moving the wires of micrometers. It is represented in Plate CCCLXXV. Fig. 6. where AB is an axis divided into three parts, *ab*, *cd*, *ef*. The screws upon the parts *ab*, *ef* have the same number of threads in an inch, and pass through two female screws in the fixed supports C, D. The axle AB moves horizontally, and any part of its axis describes at each turn of the handle H, a space equal to the distance between the threads. The middle screw *cd* has a greater or lesser number of threads in an inch than *ab* or *ef*, the difference between the two being as small as we chuse. It passes through a female screw M, which carries the moveable micrometer wire, and the piece M is prevented from turning by a groove in CD, in which its lower extremity is guided. The screw M therefore will be carried backwards towards H by the screw *cd* more or less rapidly than it advances forwards along with the axis AB, according as the number of threads in *cd* is less or greater than those in *ab* and *ef*. The threads in the screws *ab*, *ef*, may be of any magnitude, as the piece M advances or recedes in virtue of their difference. It is found difficult in practice to make the two screws *ab*, *ef*, so equal that they experience no resistance in the parts C, D; but one of the two may be suppressed, if supplied by a simple axis, which is in fact reducing it exactly to Mr Hunter's screw.

The fibres for micrometers have generally been silver wires drawn to a great degree of fineness. Muschenbroek informs us, that an artist of Nuremberg drew gold wire so fine, that 500 inches of it only weighed one grain; but he does not state by what means it was made. In 1775, Felix Fontana recommended the spider's web as a substitute for silver wire, and he is said (though we suspect an error in the statement) to have found them so small as the 8000th part of a line. The use of the spider's web was introduced by Mr. Troughton, who found it to be so fine, opaque, and elastic, as to answer all the objects of practical astronomy. He has found, however, that it is only the *stretcher*, or the long line that supports the web, which possesses these valuable properties. The facility with which fine glass fibres can at all times be obtained induced Dr. Brewster to recommend them for micrometrical fibres, and some of those which he employed were about $\frac{1}{1300}$ of an inch in diameter, bisected longitudinally with a fine transparent line about the 3000dth of an inch in diameter. Dr. Brewster sometimes employed threads of melted sealing wax. Mr. Wallace has more recently recommended the fibres of asbestos, which can be obtained to any degree of fineness.

The formation of micrometrical fibres has, however, been brought to a high degree of perfection by Dr. Wollaston, who has discovered a method of making them of any degree of fineness. Along the axis of a cylindrical mould he placed a small platinum wire, and then filled the mould with melted silver. The silver was now drawn out till it was about the 300dth part of an inch, for example, in diameter, and it is manifest, that if the platinum wire was $\frac{1}{10}$th of the diameter of the silver wire, before the operation of drawing commenced, it must be $\frac{1}{3000}$dth of an inch in diameter when the silver wire is $\frac{1}{300}$dth. In this state the silver wire, with the platinum one inclosed, is bent into the form of the letter U, making a hook at each of its ends, and in this state it is suspended by a gold wire and dipped in hot nitric acid or aquafortis. The silver is now dissolved by the nitric acid, except at its extremities, and the platinum wire remains untouched by the acid. The hooks at the end of the wire retaining the silver served to make the platinum wire visible. By this ingenious method he easily obtained platinum wires, or gold wires of $\frac{1}{3000}$ or $\frac{1}{5000}$ an inch in diameter, and, with a little attention, he formed them so small as the $\frac{1}{18000}$th part of an inch. The single lens micrometer by which Dr. Wollaston measured the diameter of these fibres, will be described in Chapter IX.

Micrometrical fibres may be placed in delicate parallel grooves formed on the diaphragm of the first eye-glass, and fixed in their places, for temporary purposes, by a thin layer of bees-wax or a drop of varnish; but when they are required to be kept at an invariable distance, it is safer to pinch them to the diaphragm by a small screw nail near the extremity of each wire. In order that the fibres may be placed exactly in the anterior focus of the eye-glass, the diaphragm should be made moveable along the axis of the eye-tube.

CHAP. III.

On Wire Micrometers, in which the scale is varied, or the Wires opened and shut optically.

The idea of varying the magnitude of the meshes of a net of silver wire, permanently fixed in the focus of the eye-glass of a telescope, for the purpose of measuring the digits of eclipses, seems to have been first suggested by M. de La Hire. The same idea afterwards occurred to the late celebrated Mr. Watt, (as he himself informed us,) who constructed a sort of micrometer upon this principle; but he never published any account of it, and did not examine its optical properties. See *Edinburgh Philosophical Journal*, vol. ii. p. 124.

The idea of opening and shutting one or more pairs of wires optically, instead of mechanically, was first applied as a general principle for micrometers by Dr. Brewster. In his treatise on *New Philosophical Instruments*, he has described various micrometers of this kind, which seem to possess properties worthy of the attention of practical astronomers; and, if we are not misinformed, one of these telescopical micrometers has been recently fitted up for use in the Observatory at Greenwich, at the desire of our celebrated astronomer royal, Mr. Pond.

"The diameter of the sun, or any portion of space, may be comprehended between a pair of fixed wires placed in the eye-piece of a telescope, either by a mechanical or an optical contrivance; in the one case, by varying the distance of the wires till they contain exactly the solar disc; and in the other, by expanding or contracting the image of the sun till it exactly fills the space between a pair of fixed wires. Thus let S′s′, Plate CCCLXXV. Fig. 7. be the sun in contact with the lower wire CD, the wire AB may be moved into the position *ab*, so as to touch the upper limb S′ of the sun; or if the wires AB, CD, are both fixed, we may, by increasing the magnifying power of the telescope, expand the image S′s′ into Ss, till its north and south limbs are in accurate contact with the fixed wires. In the first of these methods, which has been already explained in the description of the common wire micrometer, the angle subtended by the sun is measured by the revolutions of the screw, which are necessary to bring the wire AB from a state of coincidence with CD in the position *ab*:—In the second method, which is the principle on which the new instrument is founded, the angle is measured by the change of magnifying power which is required to enlarge the solar image, till its diameter is exactly equal to the distance between the wires. Though the wires are in this case absolutely fixed, yet the angle which they subtend at the observer's eye continually changes with the magnifying power of the telescope; for if the sun S′s′ fills half the space between the wires AB, CD, before the magnifying power is increased, the angle subtended by these wires must be equal to twice the diameter of the sun, or about 62 minutes; and when the solar image has been expanded to Ss, the wires AB, CD, only subtend an angle equal to the sun's diameter, or about 31 minutes; so that if this expansion of the sun's image has been produced by a gradual change in the magnifying power of the telescope, the wires must have subtended every possible angle between 31 and 62 minutes.

The gradual variation of the magnifying power, which is thus essential to the construction of the instrument, may be effected by different contrivances,—by changing the distance between the two parts of the achromatic eye-piece; by separating one or more of the lenses of the compound object glass; or by making a convex, a concave, or a meniscus lens, move along the axis the telescope, between the object glass and its principal focus.

The last of these contrivances, which is, for many reasons, preferable to any of the other two, is represented in Plate CCCLXXV. Fig. 8. where O is the object glass, whose principal focus is at *f*, and L the separate lens, which is moveable between O and *f*. The parallel rays R, R, converging to *f*, after refraction by the object glass O, are intercepted by the lens L, and made to converge to a point F, where they form an image of the object from which they proceed. The focal distance of the object glass O has therefore been diminished by the interposition of the lens L, and consequently the magnifying power of the telescope, and the angle subtended by a pair of fixed wires in the eye-piece, have suffered a corresponding change. When the lens is at *l*, in contact with the object glass, the focus of parallel rays will be about ϕ; the magnifying power will be the least possible, and the angle of the wires will be a *maximum;* and when the lens is at *l′*, so that its distance from O is equal to O*f*, the focus of parallel rays will be at *f*;—the magnifying power will be the greatest possible, and the angle of the wires will be a *minimum.* When the lens L has any intermediate position between l and l', the magnifying power and the angle of the wires have an intermediate value, which depends upon the distance of the lens from the object glass. Hence it appears, that the scale which measures these variations in the angle of the wires, may always be equal to the focal length of the object glass; and it may be shewn in the following manner, that it is a scale of equal parts, the changes upon the angle being always proportional to the variation in the position of the moveable lens.

The point f being that to which the rays incident upon L always converge, we shall have, by the principles of optics, $F+Lf:F=Lf:LF$, F being equal to the focal length of the lens L. Now it is obvious, that the magnitude of the image formed at F, after refraction through both the lenses, will be to the magnitude of the image formed at f by the object glass O, (or by both lenses when L is at l',) as LF is to Lf; for the image formed at f is the virtual object from which the image at F is formed, and the magnitude of the image is always to the magnitude of the object directly as their respective distances from the lens. Hence the magnifying power of the telescope, when the lens L is in these two positions, is in the ratio of LF to Lf, consequently the angle subtended by the wires, which must always be inversely as the magnifying power, will be as Lf to LF.

By making $Lf=b$, the preceding formula becomes $F+b:F=b:LF$. Hence $LF=\frac{Fb}{F+b}$. Then calling A the least angle subtended by the wires, or the angle which they subtend when the lens L is at l', and α the angle which they subtend when the lens is at L or in any other position, we have $A:\alpha=LF:Lf$, that is $A:\alpha=\frac{Fb}{F+b}:b$, and $\alpha=A+\frac{Ab}{F}$=the angle for any distance b. Calling P the greatest magnifying power, and π the magnifying power for any distance b, we shall have $P:\pi=b:\frac{Fb}{F+b}$, and $\pi=\frac{PF}{F+b}$= the power for any distance b. Making $A=20$, $P=20$, $F=10$, and $b=0$, 1, 2, 3, 4, successively, we obtain from these two formulæ the results in the following table.

Different values of b	Calculated magnifying powers.	Differences.	Calculated angles.	Differences.
0	20.00000		20′	
		1.81818		2
1	18.18182		22	
		1.51515		2
2	16.66666		24	
		1.28205		2
3	15.38461		26	
		1.09890		2
4	14.28571		28	

Hence it appears, that when the different values of b are in arithmetical progression, the angle α of the wires varies at the same rate, and therefore the scale which measures these angular variations is a scale of equal parts. The magnifying power, however, does not vary with equal differences, and consequently a scale for measuring its variations, if any scale were wanted, is not a scale of equal parts.

Having thus ascertained the nature of the scale, we shall now proceed to point out the method of constructing it. It is obvious that the length of the scale is arbitrary, and may be made equal either to the whole focal length Of of the object glass, or to any portion of it. If the lens L moves along the *whole* length of the axis Of, the angle subtended by the wires can be varied to a greater degree than if the lens moves only along a portion of the axis; but as this advantage may be obtained by a contrivance hereafter to be described, it will be found more convenient for astronomical purposes to make the lens moveable only along a part of the axis, as from L towards f.

Let us suppose, therefore, that when the object glass O is 36 inches in focal length, 10 inches will be a convenient length for the scale, and that the telescope is constructed so that the lens L can move freely through that space reckoned from f, the next thing to be determined is the focal length of the lens L. It is evident that a lens of 6 inches focal length will produce a much greater diminution of magnifying power, and consequently a much greater increase upon the angle of the wires in moving from f to L than a lens of greater focal length; so that the value of the whole scale in minutes or seconds, or the increase in the angle occasioned by the motion of the lens from f to L, must be inversely as the focal length of the moveable lens. If the angle of the wires is 26 minutes, for example, and if the magnifying power of the telescope is diminished from 40 to 30 by the motion of the lens from f to L; then when the lens is at L, the angle of the wires will be 34′ 40″, for 30 : 40=26′ : 34′ 40″. Hence we have a scale of 10 inches to measure 26′—34′ 40″, or 8′ 40″, and therefore every tenth of an inch on the scale will be equal to 5″.2.

If we employ a lens of much greater focal length, so as to diminish the magnifying power only from 40 to 35, and if the angle of the wires is 29 minutes; then when the lens is at L, the angle of the wires will be 33′ 9″ nearly, for 35 : 40=29′ : 33′ 9″. And hence we have a scale of 10 inches to measure 29′—33′ 9″, or 4′ 9″, consequently every tenth of an inch on the scale corresponds to 3″.3. From this it will be manifest, that the accuracy of the scale is increased by increasing the focal length of the moveable lens.

The two preceding examples are suited to a micrometer for measuring the diamaters of the sun and moon at their various distances from the earth; but, in order to show the resources of the principle on which the instrument is founded, we shall take another example, better adapted to this purpose.

Let us suppose that the pair of fixed wires subtends only an angle of 40″, for the purpose of measuring the distance between double stars, or the diameters of some of the smaller planets, that the telescope magnifies 300 times, and that the lens L in its motion from f to L, through a space of 10 inches, diminishes the power of the instrument to 240; then when the lens is at L, the angle of the wires will be 50″, for 240 : 300 = 40″ : 50″. Hence we have a scale of ten inches to measure 40″—50″, or 10″, so that every inch of the scale corresponds to 1″, and every tenth of an inch to 6‴.) From this it follows, that the accuracy of the scale increases as the angle subtended by the fixed wires diminishes.

If it should be found convenient to make each division of the scale correspond to a greater variation in the angle than in any of the examples which we have given, it would then be proper to make use of a vernier for subdividing the units of the scale.

In order to show more clearly the method of completing the scale, we have represented a telescope furnished with a micrometer, in Plate CCCLXXV. Fig. 9, where AB is the principal tube, with the object glass at B; CD a secondary tube, at the right hand extremity of which is fixed the lens L, (Fig. 8.) which is moved backwards and forwards with the tube, by the milled head F; and E the eye-piece, which is adjusted to distinct vision by the milled head G. The small index i projecting from the principal tube below A, and furnished with a vernier scale if necessary, points out the divisions on the scale. Let it now be required to construct the scale for the 2d Example, where the lens L, by moving from f to L, changes the power of the telescope from 40 to 35. Having moved the tube CD as far out as possible, by the milled head F, mark the point of it at n to which the index i points, and this will be the beginning or zero of the scale. Adjust the eye-tube E to distinct vision, and find by experiment* the angle subtended by the fixed wires: Let this angle be 29 minutes. Move the tube CD as far in as possible by means of the nut F, till the index i points to m, and mark this as the other extremity of the scale. Let the eye-tube E be again adjusted to distinct vision, and the angle subtended by the wires again determined experimentally; and let this angle be now 33′ 9″. In order to find the point of the scale corresponding to 33′, say, As 4′ 9″, the value of the whole scale is to 10 inches, the length of the scale, so is 9″ to 36 hundredths of an inch, which, being set from m to o, will mark out the point o as corresponding to 33′. The space $o\,n$ being divided into four parts for minutes, and each minute into as many divisions as possible, the micrometer will be ready for use. If great accuracy is required, every unit of the scale might be determined experimentally, by any of the methods mentioned in the preceding note. The instrument thus constructed, is capable of measuring angles only between 29′ and 33′ 9″, and is therefore peculiarly fitted for determining the diameters of the sun and moon. Its range, however, could easily have been extended, by lengthening the tube CD, or by employing a moveable lens, of smaller focal length;—or instead of one pair of wires, we might use several pairs, as AB, CD, $a\,b$, $c\,d$, $\alpha\beta$, $\gamma\delta$, (Plate CCCLXXV. Fig. 10.) so placed that only one pair should be in the field of view at a time, and that the least angle of the second pair should be equal to the greatest angle of the first pair, and the least angle of the third pair equal to the greatest angle of the second.

When the micrometer is constructed on these principles, it is certainly free from almost all those sources of error with which the wire micrometer is affected. The imperfections of the screw, the errors arising from the uncertainty of the zero, from the bad centering of the lenses, from the want of parallelism in the wires, and from the minuteness of the scale, are completely removed. Nay, if the scale is formed by direct experiments, whatever errors may exist in the instrument are actually corrected; for as the sources from which these errors proceed existed in the instrument during the formation of the scale, they cannot possibly affect the result of any observation. The scale is in fact the record of a series of experimental results, and the observation must be as free from error as the experiments by which the scale was formed. It would, therefore, be of great advantage, in micrometrical observations, to make the points B, C, (Plate CCCLXXV. Fig. 11,) with which the wires appear to come in contact, as luminous as the objects to which it is intended to apply the instrument, or rather to have a series of results for objects of various degrees of illumination.

In the preceding micrometer, the angle of a pair of fixed wires is increased and diminished by the motion of a second object-glass along the axis of the telescope; while, in the present instrument, the variation of the angle is effected by separating the two parts which compose an achromatic eye-piece; or, when the eye-piece consists of two or three lenses, by separating the lens next the eye from the remaining lenses.† If the small tube, which contains the field-glass and the first eye-glass, be pulled out beyond its natural position, the magnifying power of the instrument will be increased; and if the same tube be pushed farther in than its natural position, the magnifying power will be diminished. It will be found, in general, that if the tube already mentioned be allowed to move over the space of four inches, that is, about two inches on each side of its natural position, the magnifying power at one extremity of this space will not be very far from double of what it is at the other extremity.

* In order to find the angle subtended by a pair of wires AB, CD, Fig. 7, direct the telescope, the object-glass of which is supposed to be at the point A, Fig. 11, to any upright object MN, with a plain surface, perpendicular to the axis of the telescope, and placed at a convenient distance, 500 feet for example, and observe the space which the wires appear to occupy, or the points B, C, which the wires seem to cover, taking particular care that the line joining these points is perpendicular to the wires. Let the space BC be 4 feet 2.57 inches. Bisect BC in D, and draw DA; then, in the right angled triangle ADB, we have AD=500 feet, and BD=2 feet 1.285 inches, to determine the angle BAD, which, by the simplest case of plain trigonometry, will be found to be 14′ 30″, so that the whole angle BAC, or that subtended by the wires, will be 29′.

It is obvious, however, that on account of the proximity of the object MN, the image of it in the telescope is formed by rays which fall diverging upon the object glass O, and therefore this image will be formed at f', Fig. 8, at a greater distance than the principal focus f. Hence the magnifying power will be greater, and the angle of the wires less, than they would have been had the object MN been infinitely distant. It is necessary, therefore, to find the corrected angle BAC, so that we may have the real value of that angle when the telescope is directed to the heavenly bodies. Let O f, the focal length of O, Fig. 8, be called φ; D the distance of the object MN; a the angle found by experiment; x the correct angle; F the focal length of L; and b the distance of the lens L from the focus f. Then we have, by the principles of Optics, $\frac{\varphi^2}{D-\varphi}=ff$, the increase of focal length. Calling this value of ff' m, we have $b+m=Lf'$, and by the principles of Optics, $F+b+m : F=b+m : \frac{Fb+Fm}{F+b+m}$ for the new value of LF, or for LF′. Hence LF : LF′$=a:x$; that is, $\frac{Fb}{F+b} : \frac{Fb+Fm}{F+b+m}=a:x$; a formula from which the corrected angle x may be readily found.

† An instrument of nearly the same kind with the following, has been described by Mr. Ezekiel Walker, in the *Phil. Mag.* Aug. 1811, Vol. xxxviii. p. 127, as an invention of his own. So early as the end of the year 1805, I sent a drawing and description of the eye-piece micrometer to Mr. Carey, optical instrument maker, London. In 1806, one of the instruments made for me by Messrs. Miller and Adie, Edinburgh, was examined by Professor Playfair; and since that time it has been in the possession of a friend in London.

The eye-piece micrometer is represented in Plate CCCLXXV. Fig. 12. with all the lenses in their natural position. The part AFG, containing the two lenses A, C, is fixed to the telescope, and a space is left between the tube AC and the outer tube, in order to permit the moveable part of the eye-piece to get sufficiently near to the lens C, and also to a sufficient distance from it. The other tube DB, containing the field-glass D, and the first eye-glass B, is moved out and in by a rack and pinion E. The scale is engraven upon the upper surface $l\,n$, and the divisions are pointed out by the index of a vernier placed at the extremity m of the outer tube FG. The zero of the scale is the point marked out by the index of the vernier, when the tube DB is pushed in as far as possible; and the divisions may be read off, if necessary, by means of a convex glass at F, fixed to the tube AFG.

The value of the scale of this micrometer may be determined by direct experiment, by the methods which have already been described.

The following method, however, is more simple, and perhaps equally accurate. After having found the greatest angle subtended by a pair of wires, placed in the focus of the eye-glass, or the angle when the index is at the zero of the scale, by the method in p. 224, note, take the eye-piece out of the telescope, and having pushed the tube which contains the moveable lens or lenses as far in as possible, direct it as a microscope to a scale minutely divided.* Mark the position of the index when the wires comprehend exactly a certain number of these divisions, say 50, which they may be made to do, by a very trifling motion of the moveable tube, and make this point the zero of the scale. Let the moveable tube be now pulled out till the wires successively comprehend 48, 46, 44, 42, &c. of the divisions, or any other numbers, diminishing in arithmetical progression, and mark these points upon the tube. By this means, a scale will be formed, in which the divisions correspond to equal variations in the angle. If it should be found convenient to divide the scale into equal parts, the value of the divisions may be found in the same way.

In applying to the reflecting telescopes of Gregory and Cassegrain the principle which has been already explained, we are led to the formation of a micrometer, remarkable for the simplicity of its construction; and what, at first sight, may appear paradoxical, *we may convert a Gregorian or a Cassegrainian telescope into a very accurate micrometer, almost without the aid of any additional apparatus.*

It will be readily seen, by those who understand the theory of these telescopes, that their magnifying power may be increased merely by varying the distance between the eye-piece and the great speculum; and then producing a distinct vision by a new adjustment of the small mirror. Hence a pair of wires fixed in the eye-piece may be made to subtend different angles, solely by having that part of the instrument moveable along a portion of the common axis of the two mirrors.

In order to understand this, let SS, (Plate CCCLXXV. Fig. 13) be the great speculum of a Gregorian telescope, having a round hole in its centre, and placed at the extremity of the tube AA; and let M be the small speculum, whose focus is G, and centre H, attached to an arm MQ, and moveable along the axis of the instrument by means of a screw and milled head. The rays RR, proceeding from the lower part of any object, and falling upon the speculum SS, will be reflected to R′, and will there form an image of that part of the object. In like manner, the rays $r\,r$ will form an image of the upper part of the object at r'. The rays diverging from the image R′ r', and intercepted by the small speculum M, will form another image R″ r'', at the distance MF; which being viewed by the eye-glass at E, whose focal distance is FE, will appear distinct and magnified to the observer.

Let us now suppose that the lens E, or the eye-piece of the telescope, (which is generally a Huygenian eye-piece, with two glasses,) is moved by a suitable apparatus into the position E′, and that a point F′ is taken, so that F′ E′ may be equal to FE. Then it is manifest, that, in order to have a distinct view of the object in this new position of the eye-piece, the image formed by the small speculum must be brought to F′ in the focus of the lens E′. But as the place of the first image R′ r' is in no respects changed by the change of position in the eye-piece, the formation of the image at F can be effected only by bringing the small mirror M into a position M′, nearer the image R′ r' than it was before; and as the space MM′ through which it has been moved, in order to converge the rays to F′, must necessarily be less than FF′ = EE′, the space through which the eye-glass has moved; the distance M′ F′ of the new image at F′ from the small mirror must be greater than MF, the distance of the other image at F, in the ratio of M′ F′ to MF; and the magnifying power of the instrument must at the same time be increased, and the angle subtended by the wires diminished.

In the formation of this micrometer, we may either construct the scale from calculation, after the two extreme points of it have been fixed experimentally, by the method already described; or all the points of the scale may be determined by direct experiment. It would perhaps be more convenient to divide the scale into equal parts, and to construct a table from experiment, for the purpose of shewing, by inspection, the angle which corresponds to any number of these equal divisions."

CHAP. IV.

On Double Image Micrometers, in which the Lenses, Mirrors, and Prisms, are opened and shut mechanically.

The first hint of a double image micrometer seems to have been communicated, in 1675, by the celebrated Danish astronomer M. Roemer. It appears, however, to have remained so entirely unnoticed, that it was not even known to Mr. Servington Savary of Exeter, in the year 1743, when he communicated to the Royal Society of London an account of a double image micrometer, consisting of two lenses, capable of being separated from and of being brought near to one another by mechanical means. When the two images of the sun, or of any other body, were in contact, the distance of the lenses becomes a measure of the angular magnitude of the sun, the value of the scale having been previously

* The beautiful micrometrical scales formerly constructed by Mr. Coventry, and now by Mr. Barton, are admirably adapted for this purpose.

determined by experiment. The account of Savary's micrometer was extracted from the minutes of the Society by Mr. Short, and published in the *Phil. Trans.* for 1753. In 1748, M. Bouguer proposed a similar instrument which he called a heliometer; and in 1753, Mr. Dollond made a farther improvement on this kind of micrometer, by substituting in place of two object-glasses a single object-glass cut in two. As a drawing and description of Mr. J. Dollond's divided object-glass micrometer has already been given in our article Astronomy, and in Plate XLVIII. Fig. 4 and 5, it is unnecessary to enlarge the present article by any description of the more imperfect instruments of Savary and Bouguer. We shall content ourselves with explaining the general principle of all instruments of this kind.

Let the two semi-lenses have their centres at E and H, (Plate CCCLXXV. Fig. 14.) and their principal focus at F, and let P, Q, be two distinct objects, or the opposite limits of the same object, lying in FE, FH prolonged. The images of the two objects P, Q, formed by each semilens, will coincide at F, and therefore two images of the circular object PBQD, viz. $m\,z$ F, $p\,x$ F, will be found touching one another at F. Hence the angular measure of PQ will be equal to the angle which EH or the distance of the centres of the semi-lenses forms at F, and, as the angles measured are very small, they will always vary as EH. The angle, therefore, which corresponds to any one distance of the centres E, H, being known by the methods already described, the angle corresponding to any other distance will be obtained by simple proportion. Mr. Dollond first adapted his micrometer to the object end of a reflecting telescope; but his son afterwards applied it to achromatic telescopes.

The divided object-glass micrometer has a great superiority over the wire micrometer, in so far as it enables us to measure any diameter of the sun or moon, whatever be its inclination to the direction of their motion; whereas, in the wire micrometer, we can only measure that diameter which is perpendicular to the direction of the motion.

In order to apply the divided object-glass micrometer to determine differences of right ascension and declination, Dr. Maskelyne has pointed out the following method.

"Let H C R c, Plate CCCLXXV. Fig. 15, be the field of view, HR and C c two wires bisecting the field of view at right angles to one another, and having a motion in their own plane, turn the wires till the westernmost star (which is the best, have further to move) run along ROH; then separate the two segments, and turn about the micrometer till the two images of the same star lie in the wire C c; and then, partly by separating the segments, and partly by raising or depressing the telescope, bring the two innermost images of the two stars to appear and run along ROH, as a, b, and the vernier will give the difference of their declinations; because, as the two images of one of the stars coincided with C c, the image of each star was brought perpendicularly upon HR or to HR in their proper meridian. And, for the same reason, the difference of their times of passing the wire CO c will give their difference of right ascensions. These operations will be facilitated, if the telescope be mounted on a polar axis. If two other wires KL, MN, parallel to C c, be placed near H and R, the observation may be made on two stars, whose difference of meridians is nearly equal to HR, the diameter of the field of view, by bringing the two images of one of the stars to coincide with one of these wires. If two stars be observed, whose difference of declinations is well settled, the scale of the micrometer will be known.

It has hitherto been supposed, that the images of the two stars can be both brought into the field of view at once upon the wire HOR; but if they cannot, set the micrometer to the difference of their declinations as nearly as you can, and make the image which comes first run along the wire HOR, by elevating or depressing the telescope; and when the other star comes in, if it does not also run along HOR, alter the micrometer till it does, and half the sum of the numbers shown by the micrometer at the two separate observations of the two stars on the wire HOR will be the difference of their declination. That this should be true, it is manifestly necessary that the two segments should recede equally in opposite directions; and this is effected by Mr. Dollond in his new improvement of the object-glass micrometer.

The difference of right ascensions and declinations of Venus or Mercury in the sun's disc and the sun's limb may be thus found. Turn the wires, so that the north limb n, Plate CCCLXXV. Fig. 16, of the sun's image AB, or the north limb of the image V of the planet, may run along the wire RH, which therefore will then be parallel to the equator, and consequently C c a secondary to it; then separate the segments, and turn about the micrometer till the two images V, v, of the planet pass C c at the same time, and then, by separating the segments, bring the north limb of the northernmost image V of the planet to touch HR, at the time the northernmost limb n of the southernmost image AB of the sun touches it, and the micrometer shows the difference of declinations of the northernmost limbs of the planet and sun, for the reason formerly given, we having brought the northernmost limbs of the two innermost images V and AB to HR, these two being manifestly interior to v and the northernmost limb N of the image PQ. In the same manner, we take the difference of declinations of their southernmost limbs; and half the difference of the two measures (taking immediately one after another) is equal to the difference of the declinations of their centres, without any regard to the sun's or planet's diameters, or error of adjustment of the micrometer; for as it affects both equally, the difference is the same as if there were no error; and the difference of the times of the transits of the eastern or western limbs of the sun and planet over C c gives the difference of their right ascensions.

Instead of the difference of right ascensions, the distance of the planet from the sun's limb, in lines parallel to the equator, may be more accurately observed thus: Separate the segments, and turn about the wires and micrometer, so as to make both images V, v, Plate CCCLXXV. Fig. 17, run along HR, or so that the two intersections I, T of the sun's image may pass C c at the same time. Then bring the planet's and sun's limbs into contact, as at V, and do the same for the other limb of the sun, and half the difference gives the distance of the centre of the planet from the middle of the chord on the sun's disc parallel to the equator, or the difference of the right ascensions of their centres, allowing for the motion of the planet in the interval of the observations, without any regard to the error of adjustment, for the same reason as before. For if you take any point in the chord of a circle, half the difference of the two segments is manifestly the distance of the point from the middle of the chord; and as the planet runs along HR, (Plate CCCLXXV. Fig. 18,) the chord is parallel to the equator.

In like manner, the distances of their limbs may be measured in lines perpendicular to the equator, by bringing the micrometer into the position already described, and instead of bringing V to HR, separate the segments till the northernmost limbs coincide as at V; and in the same manner make their southernmost images to coincide, and half the difference of the two measures, allowing for the planet's motion, gives the difference of the declinations of their centres.

Hence the true place of a planet in the sun's disc may at any time of its transit be found; and consequently the nearest approach to the centre and the time of ecliptic conjunction may be deduced, although the middle should not be observed." *Phil. Trans.* 1771.

In using the divided object-glass micrometer, it has been found in practice to give different measures of the same angle at different times. This error arises from an alteration in the focus of the eye of the observer; for if the eye is not suited to see distinctly the intersection of the two pencils PF, QF, Fig. 13, at the point F, the two images will either appear separate or overlap one another, according as the eye is adapted to a nearer or a more distant object than F. In order to remedy this inconvenience, Dr Maskelyne contrived, in the year 1776, the prismatic micrometer, which we shall describe in his own words.

"Let ACB (Plate CCCLXXV. Fig. 19.) represent the object-glass, and *d* the eye-glass of a telescope, and PR a prism placed to intercept part of the rays coming from an object, suppose the sun, before they fall on the object-glass. The rays EE, proceeding from the eastern limb of the sun, and refracted through the object-glass ACB without passing through the prism, will form the corresponding point of the sun's image at *e*; and the rays WW proceeding in like manner from the western limb of the sun, will be refracted to form the correspondent point of the sun's image at *w*. But the rays 2E, 2E, 2W, 2W, proceeding in like manner from the eastern and western limbs of the sun, and falling on the prism PR, and thence refracted to the object-glass ACB, will, after refraction through it, form the correspondent points of the sun's image at 2*e*, 2*w*. Let the refraction of the prism be equal to the sun's apparent diameter: in this case, at whatever distance the prism be placed beyond the object-glass, the two images of the sun, *we*, 2*w* 2*e* will touch one another externally at the point *e*2*w*; for the rays 2W, 2W, proceeding from the western limb of the sun, being inclined to the rays EE, proceeding from the eastern limb in the angle of the sun's apparent diameter, will, after suffering a refraction in passing through the prism equal to the sun's apparent diameter, emerge from the prism, and fall upon the object-glass parallel to the rays EE, and consequently will have their focus 2*w* coincident with the focus *e* of the rays EE, and therefore the two images of the sun, *we*, 2*w*2*e*, will touch one another externally at the point *e*2*w*, and the instrument will measure the angle EC2W, and that only.

But if the prism be placed within the telescope, the angle measured by the instrument will be to the refraction of the prism as the distance of the prism from the focus of the object-glass is to the focal distance of the object-glass; or if two prisms be used to form the two images, with their refracting angles placed contrary ways, as represented in Plate CCCLXXV. Fig. 20, and 21. the angle measured will be to the sum of the refractions of the prisms as the distance of the prisms from the focus of the object-glass is to the focal distance of the object-glass. For let ACB (Fig. 20.) represent the object-glass, and *d* the eye-glass of a telescope, and PR, RS, two prisms interposed between them, with their refracting angles turned contrary ways, and the common sections of their refracting planes touching one another at R. The rays proceeding from an object, suppose the sun, will be disposed, by the refraction of the object-glass, to form an image of the sun at the focus; but part of them falling on one prism, and part on the other, will be thereby refracted contrary ways, so as to form two equal images *w e*, 2*w*2*e*, which, if the refractions of the prisms be of proper quantities, will touch one another externally at the point *e*2*w*. Let ECN be the axis of the pencil of rays EE proceeding from the sun's eastern limb; and WCO the axis of the pencil of rays WW proceeding from the sun's western limb; and the point N the place where the image of the sun's eastern limb would be formed, and the point O where that of the western limb would be formed, were not the rays diverted from their course by the refractions of the prisms. But, by this means, part of the rays EE, which were proceeding to N, falling on the prism PR, will be refracted, to form an image of the sun's eastern limb at *e*, while others of the rays EE, which fall on the prism RS, will be refracted, to form an image of the sun's eastern limb at 2*e*. In like manner, part of the rays WW, which were proceeding to form an image of the sun's western limb at O, falling on the prism RS, will be refracted, to form an image of the sun's western limb at 2*w* coincident with *e*, the point of the image correspondent to the sun's eastern limb: while others of the rays WW, which fall on the prism PR, will be refracted to form the image of the sun's western limb at *w*. The two images *w e*, 2*w*2*e*, are supposed to touch one another externally at the point *e*2*w*. The ray EFR, which belongs to the axis ECN, and is refracted by the prism PR to *e*, undergoes the refraction NR*e*, which (because small angles are proportional to their sines, and the sine of NR *e* is equal to the sine of its supplement NRC) is to NCR as NC or C *e* is to NR or R *e*. In like manner, the ray WGR, which belongs to the axis WCO, and is refracted by the prism RS to 2*w* or *e*, undergoes the refraction OR *e*, which is to OC *e* as OC or C *e* is to RO or R *e*: therefore, by composition, ORN, the sum of the refractions OR *e*, NR *e*, is to OCN, the sum of the angles OC *e*, NC *e*, or the sun's apparent diameter, as C *e* to R *e*; that is, as the focal distance of the object-glass to the distance of the prisms from the focus of the object-glass.

Or let the prisms PR, RS, be placed with their refracting angles P, S, turned from one another as in Plate CCCLXXV. Fig. 21, the refraction of the prism PR will transfer the image of the sun from ON to *w e*, and the refraction of the prism RS will transfer the image ON to 2*w*2*e*, the two images 2*w*2*e w e*, touching one another externally at the point 2*e w*. Let ECN, WCO, be the axes of the pencils of rays proceeding from the two extreme limbs of the sun, and N, O, the points where the images of the sun's eastern and western limbs would be formed by the object-glass, were it not for the refraction of the prisms; the ray EFR, which belongs to the axis ECN, and is refracted by the prism RS to $2e$, undergoes the refraction NR $2e$; and the ray WGR, which belongs to the axis WCO, and is refracted by the prism PR to w, undergoes the refraction OR w. Now NC $2e$, part of the angle measured, is to NR $2e$, the refraction of the prism RS, as R w to C w; and OC w, the other part of the angle measured, is to OR w, the refraction of the prism PR, in the same ratio of R w to C w: therefore OCN, the whole angle measured, is to ORN, the sum of the refractions of the two prisms, as R w to C w; that is, as the distance of the prisms from the focus of the object-glass to the focal distance of the object-glass.

When the prisms are placed in the manner represented in Fig 20, the point e of the image w e is illuminated only by the rays which fall on the object-glass between A and F. and the point $2w$ only by the rays which fall on the object-glass between B and G. Now the angles CRF, CRG, equal to the refractions of the prisms, being constant, the spaces FC, CG, will increase in proportion as the distances RF, RG, increase, and the spaces AF, GB, diminish as much; and therefore the images at the point of mutual contact, e 2 w, will be each illuminated by half the rays which fall on the object-glass when the prisms are placed close to the object-glass; but will be enlightened less and less, the nearer the prisms are brought to the focus of the object-glass.

But when the prisms are placed in the manner shewn in Fig. 21. the images at the point of contact, as the prisms are removed from the object-glass towards the eye-glass, will be enlightened with more than half the rays that fall on the object-glass, and will be most enlightened when the prisms are brought to the focus itself; for the point $2e$ of the image $2w2e$ will be enlightened by all the rays EE that fall on the object-glass between B and F, and the point w of the image w e will be enlightened by all the rays WW which fall on the object-glass between A and G. But the difference of the illuminations is not very considerable in achromatic telescopes, on account of the great aperture of the object-glass; as the greatest space FG is to the focal distance of the object-glass, as the sum of the sines of the refractions of the prisms is to the radius.

There is a third way, and perhaps the best, of placing the prisms, so as to touch one another along their sides which are at right angles to the common sections of their refracting planes. In this disposition of the prisms, the images will be equally enlightened, namely, each with half the rays which fall on the object-glass, wherever the prisms be placed between the object-glass and eye-glass.

From what has been shewn, it appears that this instrument, which may be properly called the prismatic micrometer, will measure any angle that does not exceed the sum of the refractions of the prisms, excepting only very small angles, which cannot be taken with it, on account of the vanishing of the pencils of rays at the juncture of the two prisms near the focus of the object-glass; that it will afford a very large scale, namely, the whole focal length of the object-glass for the greatest angle measured by it; and that it will never be out of adjustment; as the point of the scale where the measurement begins (or the point of O) answers to the focus of the object-glass, which is a fixed point for celestial objects, and a point very easily found for terrestrial objects. All that will be necessary to be done, in order to find the value of the scale of this micrometer, will be to measure accurately the distance of the prisms from the focus, when the instrument is set to measure the apparent diameter of any object subtending a known angle at the centre of the object-glass, which may be easily found by experiment, as by measuring a base, and the diameter of the object observed placed at the end of it, in the manner practised with other micrometers: for the angle subtended by this object will be to the angle subtended by a celestial object, or very remote land object, when the distance of the prisms from the principal focus is the same as it was found from the actual focus in the terrestrial experiment, as the principal focal distance of the object-glass is to the actual focal distance in the said experiment.

It will, I apprehend, be the best way in practice, instead of one prism to use two prisms, refracting contrary ways, and so divide the refraction between them (as represented in Fig. 20. and 21.) Achromatic prisms, each composed of two prisms of flint and crown-glass, placed with their refracting angles contrary ways, will undoubtedly be necessary for measuring angles with great precision by this instrument.

Two or more sets of prisms may be adapted to the same telescope, to be used each in their turn, for the more commodious measurement of different angles. Thus it may be very convenient to use one set of prisms for measuring angles not exceeding 36′, and consequently fit for measuring the diameters of the sun and moon, and the lucid parts and distances of the cusps in their eclipses; and another set of prisms to measure angles not much exceeding one minute, and consequently fit for measuring the diameters of all the other planets. This latter set of prisms will be the more convenient for measuring small angles, on account of a small imperfection attending the use of this micrometer, as before mentioned; namely, that angles cannot be measured with it when the prisms approach very near the focus of the object-glass, the pencils of rays being there lost at the point where the prisms touch one another."

This micrometer has not been found to answer in practice. In addition to the ordinary uncorrected colours of the object-glass, it is injured by the uncorrected colours of the achromatic prism, which most particularly affect the touching limbs.

A catoptric double image micrometer analogous to that of Dr. Maskelyne, but much more simple in its construction, in consequence of no additional prisms, lenses, or mirrors, being used, has lately been proposed by Dr. Brewster. It is applied to the Newtonian telescope, and has the advantage of not being affected by any change in the focal length of the eye An account of this micrometer will be found in the *Edinburgh Philosophical Journal* for 1820.

In the year 1779, the late ingenious Mr. Ramsden communicated to the Royal Society an account of two micrometers; a *catoptric* one, which formed two images by means of two semi-mirrors; and a *dioptric* one, which formed a double image by means of two semi-lenses placed in the eye-piece of the telescope

The first of these instruments is represented in Plate CCCLXXV. Fig. 22, and has been thus described by its inventor. "Beside the advantage it derives from the principle of reflection, of not being disturbed by the heterogeneity of light, it avoids every defect of other micrometers, and can have no aberration, nor any defect arising from the imperfection of materials or of execution; as the extreme simplicity of its construction requires no additional mirrors or glasses to those required for the telescope; and the separation of the images being effected by the inclination of the two specula, and not depending on the focus of any lens or mirror, any alteration in the eye of an observer cannot affect the angle measured. It has also the advantages of an adjustment, to make the images coincide in a direction perpendicular to that of their motion; and also of measuring the diameter of a planet on both sides of the zero, which will appear no inconsiderable advantage to observers who know how much easier it is to ascertain the contact of the external edges of two images than their perfect coincidence. In this micrometer, the small speculum A is divided into two equal parts; one of which is fixed on the end of the arm B, the other end of the arm is fixed on a steel axis X, which crosses the end of the telescope C. The other half of the mirror A is fixed on the arm D, which arm at the other end terminates in a socket *y*, that turns on the axis X; both arms are prevented from bending by the braces *a a*. G represents a double screw, having one part *e* cut into double the number of threads in an inch to that of the part *g*; the part *e* having 100 threads in one inch, and the part *g* 50 only. The screw *e* works in a nut F in the side of the telescope, while the part *g* turns in a nut H, which is attached to the arm B; the ends of the arms B and D, to which the mirrors are fixed, are separated from each other by the point of the double screw pressing against the stud *h*, fixed to the arm D, and turning in the nut H on the arm B. The two arms B and D are pressed against the direction of the double screw *e g*, by a spiral spring within the part *n*, by which means all shake or play in the nut H, on which the measure depends, is entirely prevented.

From the difference of the threads on the screw at *e* and *g*, it is evident that the progressive motion of the screw through the nut will be half the distance of the centres of the two halves of the mirror; and consequently the half mirrors will be moved equally in contrary directions from the axis of the telescope C.

The wheel V fixed on the end of the double screw has its circumference divided into 100 equal parts, and the index I shows the motion of the screw with the wheel round its axis, while the number of revolutions of the screw is shown by the divisions on the same index. The steel screw at R may be turned by the key S, and serves to incline the small mirror at right angles to the direction of its motion. The telescope itself has a motion round its axis for the conveniency of measuring the diameter of a planet in any direction; and the inclination of the diameter measured with the horizon is shown by a level and vernier on a graduated circle, at the breech of the telescope.

This micrometer will require a table for correcting a small error which arises from the eccentric motion of the half mirrors. By this motion their centres of curvature will approach a little towards the large mirror. The equation for this purpose in small angles is insensible; but when angles to be measured exceed ten minutes, it must not be neglected. Or, the angle measured may be corrected by diminishing it in the proportion the versed sine of the angle measured, supposing the eccentricity radius, bears to the focal length of the small mirror.

As the aberration is less in the Cassegrainian telescope than either in those of the Gregorian or Newtonian form, Mr. Ramsden preferred it for the application of this micrometer, the aberrations being nearly as 3 to 5.

Mr. Ramsden's dioptric micrometer, represented in Fig. 24, is applied to the erect eye-tube of a refracting telescope, and is placed between the third and fourth eye-glasses. In order to understand its application, let *x y*, Fig. 23, be the principal pencil of rays from the object-glass O; *t t* and *u u*, the axis of two oblique pencils; *a*, the first eye-glass; *m*, its conjugate focus, or the place of the micrometer; *b* the second eye-glass; *c* the third, and *d* the fourth, or that which is nearest the eye. Let *p* be the diameter of the object-glass, *e* the diameter of a pencil at *m*, and *f* the diameter of the pencil at the eye; it is evident, that the axes of the pencils from every part of the image will cross each other at the point *m*; and *e*, the width of the micrometer-glass, is to *p*, the diameter of the object-glass, as *m a* is to *g o*, which is the proportion of the magnifying power at the point *m*; and the error caused by an imperfection in the micrometer-glass placed at *m* will be to the error, had the micrometer been at O, as *m* is to *p*.

The micrometer itself is shewn in Fig. 24, where A is a convex or concave lens, bisected by a plane across its centre; one of these semi-lenses is fixed in a frame B, and the other in the frame E; which two frames slide on a plate H, and are pressed against it by thin plates *a a*: the frames B and E are moved in contrary directions by turning the button D: L is a scale of equal parts on the frame B; it is numbered from each end towards the middle. There are two verniers on the frame E, one at M, and the other at N, for the convenience of measuring the diameter of a planet, &c. on both sides the zero. The first division on both these verniers coincides at the same time with the two zeros on the scale L; and if the frame is moved towards the right, the relative motion of the two frames is shown on the scale by the vernier M; but if the frame B be moved towards the left, the relative motion is shown by the vernier N. This micrometer has a motion round the axis of vision, for the convenience of measuring the diameter of a planet, &c. in any direction, by turning an endless screw F, and the inclination of the diameter, which is measured to the horizon, is shown in the circle *g* by a vernier image. CHAP. V.

On Double Image Micrometers, in which the Lenses or Mirrors are opened and shut optically.

The method of varying the angular distance of a pair of fixed wires has been successfully applied by Dr. Brewster to the construction of a divided object-glass micrometer, which possesses peculiar advantages. It is represented in Plate CCCLXXVI. Fig. 1, where LL is an achromatic object-glass, having two achromatic semi-lenses, A, B, represented in Fig. 2.

moveable between it and its principal focus f. These semilenses are completely fixed, so that their centres are invariably at the same distance; but the angle subtended by the two images which they form, is varied by giving them a motion along the axis O f of the lens LL. When the semilenses are close to LL, the two images are much separated, and form a great angle; but, as the lenses are moved towards f, the centres of the images gradually approach each other, and the angle which they form, is constantly increasing. By ascertaining, therefore, experimentally, the angle formed by the centres of the images, when the semilenses are placed close to LL, and also the angle which they subtend when the semilenses are at f, the other extremity of the scale, we have an instrument which will measure, with the utmost accuracy, all intermediate angles.

In constructing this micrometer for astronomical purposes, the semilenses may be made to move only along a portion of the axis O f, particularly if the instrument is intended to measure the diameters of the sun and moon, or any series of angles within given limits. By increasing the focal length of the semilenses, or by diminishing the distance between their centres, the angles may be made to vary with any degree of slowness, and of course each unit of the scale will correspond to a very small portion of the whole angle. The accuracy and magnitude of the scale, indeed, may be increased without limit; but it is completely unnecessary to carry this any farther than till the error of the scale is less than the probable error of observation.

Let us now examine the theory of this micrometer, and endeavour to ascertain the nature of the scale for measuring the variations of the angle. For this purpose, let LL, Fig. 1, be the object-glass, which forms an inverted image, $m\,n$, of the object MN, and let the semilenses AB, having their centres at an invariable distance, be interposed between the object-glass and its principal focus, in such a manner, that their centres are equidistant from the axis O f. Now, it is obvious, that the size of the image $m\,n$ is proportional to the size of the object MN; and, as the angle subtended by MN depends upon its size, the magnitude of the image $m\,n$ may, in the case of small angles, be assumed as a measure of the angle subtended by MN. As the rays which proceed from the point M are all converged to m by means of the lens LL alone, the ray b A, which passes through the centre of the semilens A, must of course have the direction $b\,m$; and, as it suffers no refraction in passing through the centre of A, it will proceed in the same direction b A m, after emerging from the semilens, and will cross the axis at F. For the same reasons the ray c B, proceeding from N, and passing through the centre of B, will cross the axis at F, as it advances to n. If the distance of F from A and B happens to be equal to the focal length of the lenses A and B, when combined with LL, distinct images of M and N will be formed at F, and they will appear to touch one another; and the line $m\,n$, being the size of the image that would have been formed by the lens LL alone, will be a measure of the angle subtended by the points M, N. If the point F, where the lines A m, B n cross the axis, should not happen to coincide with the focus of the lenses A, B, when combined with LL, then let this focus be at F′, nearer A and B than F. Draw the lines AF′ m, BF′ n, then it is obvious, that if the angle subtended by MN were enlarged, so as to be represented by $n'\,m'$, instead of $n\,m$, or so that the lens LL alone would form an image of it equal to $n'\,m'$, the point of intersection F would coincide with the focus F; so that, in every position of the lenses A, B, with respect to LL, the points M, N may always be made to subtend such an angle, that when they are placed before the telescope, the points F, F′ will coincide, and consequently the images of the points M, N will be distinctly formed at F′, and will be in contact. Whenever this happens, the space $n'\,m'$ will be a measure of the angle thus subtended by MN. Hence, it follows, that whatever be the position of the semilenses A, B, on the axis O f, the rays b A, c B, which pass through the centres of the semilenses, will cross the axis at some point F, corresponding with the focus of rays diverging from M, N, and will mark out the size of the image $n'\,m'$, and consequently the relative magnitude of the angle subtended by the two points M, N.

From the equality of the vertical angles AF′ B, n' F′ m', and the parallelism of the lines AB, $n'\,m'$, we shall have $n'\,m' : \mathrm{AB} = f\mathrm{F}' : \mathrm{GF}'$; and calling $f\mathrm{F}' = b$, and considering that $\mathrm{GF}' = \frac{\mathrm{F}\,b}{\mathrm{F}+b}$, F being the focal length of the semilenses, we have $n'\,m' : \mathrm{AB} = b : \frac{\mathrm{F}\,b}{\mathrm{F}+b}$, and consequently $n'\,m' = \mathrm{AB} + \frac{\mathrm{AB}\times b}{\mathrm{F}}$. Now, calling AB=2, F=10, and b=1, 2, 3, successively, we shall obtain

$$n'\,m' = 2 + \frac{2\times 1}{10} = 2.2$$

$$n'\,m' = 2 + \frac{2\times 2}{10} = 2.4$$

$$n'\,m' = 2 + \frac{2\times 3}{10} = 2\ 6$$

faom which it appears, that when b is in arithmetical progression, the angle $n'\,m'$ varies at the same rate, and consequently the scale which measures the variations of the angle, subtended by the centres of the two images, is a scale of equal parts.

This instrument undergoes a very singular change, when constructed as in Plate CCCLXXVI Fig. 3, so that the semilenses are outermost and immoveable, while another lens, LL, is made to move along the axis G f. In this case, a double image is formed as before, but the angle subtended by the centres of the images never suffers any change during the motion of the lens LL along the axis of the telescope. If the two images are in contact when the lens LL is close to the semilenses, they will continue in contact in every other position of LL; but the magnitude of the images is constantly increasing during the motion of LL towards f, the principal focus of the semilenses. The reason of this remarkable property will be understood from Fig. 3, where M, N, are two objects placed at such an angle, that the rays passing through the centres A, B, of the semilenses, cross the axis at F, the focus of the combined lenses for rays divergent from M and N In this case, distinct images of M and N will be formed at F, and will consequently be in contact If the lens LL is removed to the position L′ L′, the rays M m, N n, which are incident upon it at the points m and n, having the same degree of convergency as before, will be refracted to F′, the focus of the combined lenses for rays diverging from MN. Two distinct images of the object will therefore be formed at F′, and these images will still be in contact. In like manner, it may be shewn, that whatever be the position of the lens LL between G and *f*, the rays M*f*, N*f*, will cross the axis at a point coincident with the focus of the combined lenses, and will there form two images always in contact. Hence it follows, that though the magnifying power of the instrument is constantly changing with the position of the lens LL, yet the angle subtended by the centres of the two images never suffers the least variation.

The application of the divided object-glass micrometer to a telescope for measuring distances, and to a coming-up glass for ascertaining whether a ship is approaching to, or receding from, the observer, will be found in Dr. Brewster's *Treatise on New Philosophical Instruments*, Book III Chap II

The principle upon which this instrument is founded may also be applied to Ramsden's dioptric micrometer, and to the reflecting micrometer which we have described in Chap. III. as applied to a Cassegrainian or Gregorian telescope.

CHAP. VI.

On Angular or Position Micrometers.

The first micrometer of this kind, that we are acquainted with, was invented and used by Sir William Herschel, for the purpose of measuring the angle which a line joining the two stars that compose a double star, forms with the direction of their apparent motion. The object which this celebrated astronomer had in view, was to verify a conjecture that the smaller of the two stars revolved round the greater, or rather round their common centre of gravity; and he actually found, by means of this instrument, that in the double star of Castor this revolution was performed in 342 years.

"The position micrometer is shown in Plate CCCLXXVI. Fig. 4, inclosed in a turned case of wood, as it is put together ready to be used with the telescope. A is a little box which holds the eye-glass. B is the piece which covers the inside work, and the box A is screwed into it. C is the body of the micrometer containing the brass work, showing the index plate *a* projecting at one side, where the case is cut away to receive it. D is a piece, having a screw *b* at the bottom, by means of which the micrometer is fastened to the telescope. To the piece C is given a circular motion, in the manner the horizontal motion is generally given to Gregorian reflectors, by the lower part going through the piece D, where it is held by the screw E, which keeps the two pieces C and D together, but leaves them at liberty to turn on each other

Fig. 5, is a section of the case containing the brass work, where may be observed the piece B hollowed out to receive the box A, which consists of two parts inclosing the eye lens. This figure also shows how the piece C passes through D, and is held by the ring E: the brass work, consisting of a hollow cylinder, a wheel and pinion, and index plate, is there represented in its place. F is the body of the brass work, being a hollow cylinder with a broad rim C at the upper end; this rim is partly turned away to make a bed for the wheel *d*. The pinion *e* turns the wheel *d*, and carries the index plate *a*. One of its pivots moves in the arm *f*, screwed on the upper part of *c*, which arm serves also to confine the wheel *d* to its place on *c*. The other pivot is held by the arm *g* fastened to F.

Fig. 6, is a plan of the brass work. The wheel *d*, which is in the form of a ring, is laid on the upper part of F or C, and held by two small arms *f* and *h* screwed down to *e* with the screws *i*, *i*.

Fig. 7, is a plan of the brass work; *d*, *d* is the wheel placed on the bed or socket of the rim of the cylinder *c*, *c*, and is held down by the two pieces *f*, *h*, which are screwed on *c*, *c*. The piece *f* projects over the centre of the index plate to receive the upper pivot of the pinion *m*, *n*, the fixed wire fastened to *c*, *c* *o*, *p*, the moveable wire fastened to the annular wheel *d*, *d*. The index plate *a* is divided into 60 parts, each sub-divided into two, and milled on the edge. When the finger is drawn over the milled edge of the index plate from *q* towards *r*, the angle *mso* will open, and if drawn from *r* towards *q*, it will shut again. The case *c*, *c*, must have a sharp corner *t*, which serves as a hand to point out the divisions on the index plate." *Phil. Trans.* 1781, p. 509.

In this instrument, the two wires always cross each other at the centre of the field, and consequently their angular separation is produced uniformly by the motion of the pinion. This very circumstance, however, which, though it renders it easy for the observer to read off the angle from the scale, is one of the greatest imperfections of the instrument. The observations must obviously be all made on one side of the centre of the field, as appears from Plate CCCLXXVI. Fig. 8, and the use of the instrument is limited to those cases in which S *s* is less than the radius SC The greatest disadvantage of the instrument, however, is the shortness of the radius SC, for the error of observation must always diminish as the length of this radius increases. This disadvantage does not exist in measuring the angle of position of two stars S. *s*, for the distance S *s* remains the same whatever be the length of SC, but in determining all other angles contained by lines, whose apparent length is greater than SC, this imperfection is inseparable from the instrument. Nay, there are some cases in which the instrument completely fails; as, for instance, when we wish to measure the angle formed by two lines which do not meet in a point, but only tend to a remote vertex. If the distance of the nearest extremities of these lines is greater than the chord of the angle which they form, measured upon the radius SC, then it is impossible to measure that angle, for the lines cannot be brought to coincide with the two lines by which it is contained. Nay, when the chord of the angle does exceed the distance between the nearest extremities, the portion of the wires that can be brought into coincidence with the lines is so small, as to lead to very serious errors in the result

The new angular micrometer, which we venture to propose as a substitute for this instrument, is completely free from the defects which we have just noticed, and is founded on a very beautiful property of the circle. If any two chords AB, CD, Plate CCCLXXVI. Fig. 9, intersect each other in the point O within the circle, the angle which they form at O will be equal to half the sum of the arches AC, BD; but if these chords do not intersect each other within the circle, but tend to any point

O without the circle, as in Fig. 10, then the angle which they form is equal to half the difference of the arches AC, BD; that is, calling ϕ the angle, we have in the first case $\phi = \frac{AC+BD}{2}$, and in the second case $\phi = \frac{AC-BD}{2}$. Hence if AB, CD be two wires, placed in the focus of the first eye-glass of a telescope, the moveable one AB may be made to form every possible angle with the fixed one CD, and that angle may be readily found from the arches AB, CD.

The apparatus by which these arches are measured is represented in Plate CCCLXXVI. Fig. 11, where the graduated circular head may be divided only into 180°, in order to save the trouble of halving the sum, or the difference of the arches AC, BD; but as it would still be necessary to measure *two* arches before the angle could be ascertained, we have adopted another method, remarkable for its simplicity, and giving no more trouble than if the wires always intersected each other in the centre of the field.

Let AB, for example, Plate CCCLXXVI. Fig. 9. be the fixed wire, and CD the moveable one, and let it be required to find, at one observation, the angle AOC or φ. Let the index of the vernier be at zero, when the point D coincides with B; and as it is obvious that the extremity C will be at c when D is at B, the arch c A will be a constant quantity, which we shall call b. Making AC $=m$ and BD$=n$, we have, $\varphi = \frac{m+n}{2}$; but since the extremity C will move over the space C c while D describes the space DB, these arches must be equal, consequently $b = m - n$; hence, adding 2 n to each side of the equation, we obtain $b + 2n = m + n$, or $\frac{1}{2} b + n = \frac{m+n}{2}$, consequently $\varphi = \frac{1}{2} b + n$. Hence the angle AOC is equal to half the arch A c added to the arch DB; or since A c is invariable, the half of it is a constant quantity, and the angle required is equal to the sum of this constant quantity and the arch DB.

When the wires do not intersect each other, as in Fig. 10, we have $\varphi = \frac{m-n}{2}$ and $b = m + n$; hence, subtracting 2 n from each side of the equation, we have $b - 2n = m - n$, and dividing by 2 $\frac{1}{2} b - n = \frac{m-n}{2}$, consequently $\varphi = \frac{1}{2} b - n$. That is, the angle AOB is equal to the difference between half the arch A c and the arch DB, or to a constant quantity, diminished by the arch DB.

In finding the angle AOB, therefore, we have merely to observe the place of the index when the wires are in their proper position; and as the scale commences at B, or when D and B coincide, and is numbered both ways from B, the degree pointed out on the circular head, when increased or diminished by the constant quantity, will give the angle of the wires which is sought. The semicircle on each side of a diameter drawn through B, is divided into 180°, the 180th degree being at the opposite end of that diameter.

The method of reading off the angle AOB may be still farther simplified, so as to save the trouble even of recollecting the constant quantity, and of adding and subtracting it from the arch pointed out by the index of the vernier. This effect is produced by making the index of the vernier point to the constant quantity upon the part of the scale below B, Fig. 9, when the points D, B, coincide, or when the wire CD is in the position c B; for it is obvious that if z is the zero of the scale, and B z equal to the constant quantity, the arch D z, which is pointed out by the index of the vernier, will be equal to $\frac{1}{2} b + n$, or the angle AOB. In like manner, in Fig. 10, where the wires do not cross each other within the field, and where B z is the constant quantity, the arch D z, marked out by the index of the vernier, is obviously equal to $\frac{1}{2} b - n$, or the angle AOB, which the wires tend to form at O. By means of this adjustment, therefore, we are enabled to read off the angle AOB with the same facility as if the wires intersected each other in the very centre of the field, when the arches are accurate measures of the angles at the centre.

It is not necessary that the two wires should be placed in the focus of the first eye-glsss. Dr. Brewster has constructed an instrument of this kind, in which the fixed wire AB is placed in the focus of the whole eye-piece, or, what is the same thing, in the focus of the object-glass, while the moveable wire CD revolved in the focus of the first eye-glass. In this case the wire AB is more magnified than the other; but if this should be regarded as an inconvenience, it might easily be removed by using a more delicate fibre.

The end of the eye-tube is represented in Fig. 11, where CD is the circular head, divided into 360°, and subdivided by the vernier V; L is the level, and AB the part of the eye-piece which contains the diaphragm with the fixed and moveable wires. The head CD, and the level L, are firmly fixed to the eye-tube T, and from the head CD there rises an annular shoulder concentric with the tube, and containing the diaphragm across which the fixed wire is stretched. This diaphragm, which is represented in Plate CCCLXXVI. Fig. 12. with the wire extended across, projects through the circle of brass EF. All these parts remain immoveable, while the outer tube AB, and the other half EF of the circular head which contains the vernier V, have a rotatory motion upon the shoulder which rises from CD. The tube AB is merely an outer case to protect a little tube within it, which contains the eye-glass, and the moveable diaphragm with its fibre extended across it. The inclosed tube is screwed into the ring EF, and the outer tube is also screwed upon the same ring; so that by moving AB, a motion of rotation is communicated to the vernier V, and to the diaphragm and wire belonging to the inner tube, while the rest of the eye-piece, containing the other diaphragm with its wire, remains stationary. By this means the moveable wire is made to form every possible angle with the fixed wire, and the angle is determined by the method which we have already explained. The fixed wire is placed a little out of the centre of the diaphragm to which it belongs, and the diaphragm itself is placed in a cell, in which it can be turned round, so as to adjust the wire to a horizontal line, when the level is set. The moveable wire is likewise placed at a little distance from the centre of its diaphragm, as represented in Plate CCCLXXVI. Fig. 13; but by means of screws which pass through the inner tube into the edge of this diaphragm, it can be moved in a plane at right angles to the axis of the eye-piece, so that the moveable wire may be placed either in the centre of the field, or at different distances from it. See *Treatise on New Phil. Inst.* p. 112.

CHAP. VII.

On Lucid Disc, and Luminous Image Micrometers.

In measuring the distance of close double stars, Sir William Herschel found it difficult to apply the common wire micrometer, from the various sources of imperfection to which it is liable, but particularly from the necessity of illuminating the wires. He, therefore, set himself to construct a micrometer for this particular purpose, and in this way he contrived the lamp micrometer.

This instrument is represented in Plate CCCLXXVI. Fig. 14. "where ABGCFE is a stand nine feet high, on which a semicircular board *q h o g p* is moveable upward or downward, in the manner of some fire-screens, as occasion may require, and is held in its situation by a peg *p* put into any one of the holes of the upright piece AB. This board is a segment of a circle of 14 inches radius, and is about three inches broader than a semicircle, to give room for the handles *r* D, *e* P, to work. The use of this board is to carry an arm L, 30 inches long, made to move on a pivot at the centre of the circle, by means of a string, which passes in a groove on the edge of the semicircle *p g o h q*; the string is fastened to a hook *o*, (not expressed in the figure, being at the back of the arm L,) and, passing along the groove from *o h* to *q*, is turned over a pulley at *q*, and goes down to a small barrel *e*, within the plane of a circular board, where a double jointed handle *e* P commands its motion. By this contrivance we see the arm L may be lifted up to any altitude from the horizontal position to the perpendicular, or be suffered to descend by its own weight below the horizontal to the reverse perpendicular situation. The weight of the handle P is sufficient to keep the arm in any given position; but if the motion should be too easy, a friction spring applied to the barrel will moderate it at pleasure.

In front of the arm L a small slider, about three inches long, is moveable in a rabbet from the end L towards the centre, backward and forward. A string is fastened to the left side of the little slider, and goes towards L, where it passes round a pulley at *m*, and returns under the arm from *m n*, towards the centre, where it is led in a groove on the edge of the arm, which is of a circular form, upward to a barrel (raised above the plane of the circular board) at *r*, to which the handle *r* D is fastened. A second string is fastened to the slider, at the right side, and goes towards the centre, where it passes over a pulley *n*, and the weight *w*, which is suspended by the end of the string, returns the slider towards the centre, when a contrary turn of the handle permits it to act.

Two small lamps, 2 inches high, $1\frac{1}{2}$ in breadth, by $1\frac{1}{4}$ in depth, are shown at *a* and *b*. The sides, back, and top, are made so as to permit no light to be seen, and the front consists of a thin brass sliding door. The flame in the lamp *a* is placed $\frac{5}{10}$ths of an inch from the left side, $\frac{3}{10}$ths from the front, and half an inch from the bottom. In the lamp *b* it is placed at the same height and distance, measuring from the right side. The wick of the flame consists only of a very thin lamp-cotton thread; for the smallest flame being sufficient, it is easier to keep it burning in so confined a place. In the top of each lamp must be a little slit, lengthways, and also a small opening in one side near the upper part, to permit air enough to circulate, to feed the flame. To prevent every reflection of light, the side opening of the lamp *a* should be to the right, and that of the lamp *b* to the left. In the sliding door of each lamp is made a small hole with the point of a very fine needle, just opposite the place where the wicks are burning, so that when the sliders are shut down, and every thing dark, nothing shall be seen but two fine lucid points of the size of two stars of the third or fourth magnitude. The lamp *a* is placed so, that its lucid point may be in the centre of the circular board, where it remains fixed. The lamp *b* is hung to the little slider which moves in the rabbet of the arm, so that its lucid point, in a horizontal position of the arm, may be on a level with the lucid point in the centre. The moveable lamp is suspended on a piece of brass fastened to the slider by a pin exactly behind the flame on which it moves as a pivot. The lamp is balanced at the bottom by a leaden weight, so as always to remain upright, when the arm is either lifted above, or depressed below the horizontal position. The double-jointed handles *r* D, *e* P, consist of light deal rods, ten feet long, and the lowest of them may have divisions, marked on it near the end P, expressing exactly the distance from the central lucid point, in feet, inches, and tenths.

From this construction we see, that a person at a distance of ten feet may govern the two lucid points, so as to bring them into any required position, south or north, preceding or following, from 0° to 90°, by using the handle P, and also to any distance from $\frac{6}{10}$ths of an inch to 5 or 6 and 20 inches, by means of the handle D. If any reflection or appearance of light should be left from the top or sides of the lamps, a temporary screen, consisting of a long piece of pasteboard, or a wire frame covered with black cloth, of the length of the whole arm, and of any required breadth, with a slit of half an inch broad in the middle, may be affixed to the arm by four bent wires, projecting an inch or two before the lamps, situated so that the moveable lucid point may pass along the opening left for that purpose.

Plate CCCLXXVI. Fig. 15. represents part of the arm L, of a larger size; *s* the slider; *m* the pulley, over which the chord *x l y z* is returned towards the centre; *v* the other chord going to the pulley *n* of Fig. 14; R the brass piece moveable on the pin *c*, to keep the lamp upright. At R is a wire rivetted to the brass piece, on which is held the lamp by a nut and screw. Fig. 16, 17. represent the lamps *a*, *b*, with the sliding doors open, to show the situation of the wicks. *w* is the leaden weight, with a hole in it *d*, through which the wire R of Fig. 15. is to be passed, when the lamp is to be fastened to the slider *s*. Fig. 18. represents the lamp *a* with the sliding door shut; *l* the lucid point; *i k* the openings at the top, and *s* at the sides for the admission of air.

The ingenious artist will soon perceive that the motions of this micrometer are capable of great improvement by the application of wheels and pinions, and other well known mechanical resources; but, as the principal object is only to be able to adjust the two lucid points to the required position and distance, and to keep them there for a few minutes, while the observer goes to measure their distance, it will not be necessary to say more on the subject.

Sir William Herschel next proceeds to show the application of this instrument. It is well known to opticians, and others, who have been in the habit of using optical instruments, that we can with one eye look into a microscope or telescope, and see an object much magnified, while the naked eye may see a scale on which the magnified picture is thrown. In this manner Sir W. Herschel generally determined the power of his telescopes; and any one who has acquired a facility of taking such observations will very seldom mistake so much as one in fifty in determining the power of an instrument, and that degree of exactness is fully sufficient for the purpose.

The Newtonian form is admirably adapted to the use of this micrometer; for the observer stands always erect, and looks in a horizontal direction, though the telescope should be elevated to the zenith. Besides, his face being turned away from the object to which his telescope is directed, this micrometer may be placed very conveniently, without causing the least obstruction to the view: therefore, in using this instrument, it is put at ten feet distance from the left eye, in a line perpendicular to the tube of the telescope, and the moveable board raised to such a height, that the lucid point of the central lamp may be on a level with the eye. The handles, lifted up, are passed through two loops fastened to the tube, just by the observer, so as to be ready for his use. It should be observed, that the end of the tube is cut away, so as to leave the left eye entirely free to see the whole micrometer.

Having now directed the telescope to a double star, it is viewed with the right eye, and at the same time with the left see it projected on the micrometer; then, by the handle P, which commands the position of the arm, it is raised or depressed so as to bring the two lucid points to a similar situation with the two stars; and, by the handle D, the moveable lucid point is approached or removed to the same distance of the two stars, so that the two lucid points may be exactly covered by, or coincide with the stars. A little practice in this business soon makes it easy, especially to one who has already been used to look with both eyes open.

What remains to be done is very simple. With a proper rule, divided into inches and 40th parts, the distance of the lucid points is taken, which may be done to the greatest nicety, because, as observed before, the little holes are made with the point of a very fine needle. The measure thus obtained is the tangent of the magnified angle under which the stars are seen, to a radius of 10 feet; therefore, the angle being found, and divided by the power of the telescope, gives the real angular distance of the centres of a double star. For instance, Sept. 25, 1781, Sir William Herschel measured α Herculis with this instrument. Having caused the two lucid points to coincide exactly with the stars centre on centre, he found the radius, or distance of the central lamp from the eye, 10 feet 4.15 inches; the tangent or distance of the two lucid points 50.6 fortieth parts of an inch; this gives the magnified angle 35′, and dividing by the power 460, which he used, he obtained 4″ 34‴ for the distance of the centres of the two stars. The scale of the micrometer at this very convenient distance, with the power of 460 (which his telescope bears so well on the fixed stars that for near a twelvemonth past he hardly used any other) is above a quarter of an inch to a second; and by putting on his power of 932, which in very fine evenings is extremely distinct, he obtained a scale of more than half an inch to a second, without increasing the distance of the micrometer; whereas the most perfect of his former micrometers, with the same instrument, had a scale of less than the 2000th part of an inch to a second.

The measures of this micrometer are not confined to double stars only, but may be applied to any other objects that require the utmost accuracy, such as the diameters of the planets or their satellites, the mountains of the moon, the diameters of the fixed stars, &c. For instance, Oct. 22, 1781, Sir William Herschel measured the apparent diameter of α Lyræ; and judging it of the greatest importance to increase his scale as much as convenient, he placed the micrometer at the greatest convenient distance and (with some trouble, for want of longer handles, which might easily be added) took the diameter of this star, by removing the two lucid points to such a distance as just to inclose the apparent diameter. When he measured his radius, it was found to be 22 feet 6 inches. The distance of the two lucid points was about three inches; for extreme nicety could not be obtained in this observation, on account of the very great power he used, which was 6450. From these measures we have the magnified angle 38′ 10″: this divided by the power gives 0″.355 for the apparent diameter of α Lyræ. The scale of the micrometer, on this occasion, was no less than 8.443 inches to a second, as will be found by multiplying the natural tangent of a second with the power and radius in inches. In Nov. 1781, he measured the diameter of the new star; but the air was not very favourable, for this singular star was not so distinct with 227 that evening as it generally is with 460: therefore, without laying much stress on the exactness of the observation, he only reports it, to exemplify the use of his micrometer. His radius was 35 feet 11 inches. The diameter of the star, by the distance of the lucid points, was 2.4 inches, and the power he used 227: hence the magnified angle is found 19′, and the real diameter of the star 5″.022. The scale of this measure is .474 millesimals of an inch, or almost half an inch to a second."

A lucid disc micrometer was also used by M. Schroeter of Lilienthal, in his observations on the new planets, but we are not acquainted with the principles of its construction.

A luminous image micrometer, in which the angle, subtended by two lucid points, is measured by expanding them into circular discs, and marking the instant of contact, has been described by Dr. Brewster in his *Treatise on New Philosophical Instruments*, p. 40.

CHAP. VIII.

On Doubly Refracting Micrometers.

The first person who proposed to employ the separation of two images, formed by double refraction, as the principle of a micrometer, was the late ingenious Abbé Rochon. On the 5th March 1777, Messrs. Leroi, Lemonnier, and Condorcet, gave a favourable report of this new invention, which was brought to a considerable degree of perfection by successive improvements, with which M. Rochon was constantly occupied till the time of his death, which took place in 1817.

If we suppose ABC, (Plate CCCLXXVI. Fig. 19.) a prism of rock crystal, so cut out of the hexaedral prism in which this substance is generally formed, that AC is the axis of the prism, and BCD another prism, so cut out of the same crystal, that BC is the axis of the prism, then a ray of light RR incident perpendicularly at R, will go on to R′ without being divided into two pencils, as the doubly refracting force vanishes in the direction of the axis; but when it reaches R′ it will be divided into two pencils R′ R″, R′ ϱ, one of which, R R″, the ordinary pencil, will go on in the direction R′ E without any deviation, as it is in no way affected with the doubly refracting force of the second prism BCD, while the extraordinary pencil R′ ϱ will deviate from the line R′ E, in virtue of the doubly refracting force of the second prism BCD. An eye placed at E will obviously not receive the two rays R′ E and R′ ϵ, but if we draw E r'', r'' r', r' r respectively parallel to ϵ ϱ, ϱ R′, r'' R′ R, a ray r r incident perpendicularly at r, will give an extraordinary ray r'' E, which will reach the eye E at the same time with the ordinary ray R′ E, and the observer will see two distinct images of the object from which these rays proceed.

In order to apply this compound prism to the purposes of a micrometer, M. Rochon introduces it between the object-glass and the eye-glass of an astronomical telescope, as shown in Plate CCCLXXVI. Fig. 20; and by moving it along the axis of the telescope, the angular separation of the two images of the object s s' is made to vary in a manner similar to what has been already described in the prismatic micrometer of Dr. Maskelyne.

In the year 1812, M. Rochon proposed another form of his micrometer, from which he expected great advantages. He took a parallelopiped of rock crystal, formed of two prisms, cut with angles of about 30°, and so as to make the images of the sun overlap one another about five minutes. When joined together by mastic, it was ground into a convex lens, and was united with a concave lens of glass, so as to form an achromatic object-glass. The object-glass, which had a focal length of about three decimeters, separated the centres of the images of the sun about 28 minutes. He then adapted to this object-glass a common micrometer, which measured angles of 10 minutes, and he had thus three decimetres or 10 minutes to complete the measure of the diameters of the sun or moon.

Ingenious as these micrometers are, we conceive them to be liable to an objection of a very serious nature. Dr. Brewster has shown, from numerous experiments, that rock crystal is very imperfectly crystallized in the direction of its axis, and that it exhibits great deviations from a homogeneous texture, both in its action upon common and polarised light. Distinct images therefore cannot be formed through prisms or lenses whose refracting surfaces are perpendicular, or nearly so, to the axis of the hexaedral prism. If astronomy therefore is to derive any advantage from doubly refracting micrometers, we must have recourse to the double refraction of other substances than rock crystal.

CHAP. IX.

On Micrometers for Microscopes.

Microscopical micrometers are generally employed for measuring very minute spaces, such as the subdivisions of astronomical instruments, or the diameters of objects magnified in the field of a microscope. All the micrometers described in chapter first, may be considered as micrometers of this kind, when placed in the anterior focus of the eye-glass of a microscope.

One of the simplest micrometers for microscopes, consists of a screw with an index, fixed in the focus of the eye-glass. The point of the screw is made to move across the space to be measured; and as the index registers the number of revolutions necessary for this purpose, the diameter of the object will be found by ascertaining the number of threads in one inch.

Dr. Jurin measured the magnitudes of minute objects, by comparing them with small pieces of silver or brass wire placed beside them; the diameter of which had been previously ascertained by coiling it round a cylinder, and observing how many breadths of the wire were contained in a given number of inches.

One of the best microscopical micrometers is the single lens micrometer, invented by Dr. Wollaston. This instrument, says Dr. Wollaston, is furnished with a single lens of about $\frac{1}{12}$th of an inch focal length. The aperture of such a lens is necessarily small, so that when it is mounted on a plate of brass, a small perforation can be made by the side of it in the brass, as near to its centre as $\frac{1}{25}$th of an inch.

When a lens thus mounted is placed before the eye for the purpose of examining any small object, the pupil is of sufficient magnitude for seeing distant objects at the same time through the adjacent perforation, so that the apparent dimensions of the magnified image might be compared with a scale of inches, feet, and yards, according to the distance at which it might be convenient to place it.

A scale of smaller dimensions attached to the instrument will, however, be found preferable on account of the steadiness with which the comparison may be made; and it may be seen with sufficient distinctness by the naked eye, without any effort of nice adaptation, by reason of the smallness of the hole through which it is viewed.

The construction that I have chosen for the scale is represented in Plate CCCLXXVI. Fig. 21. It is composed of smalls wires about $\frac{1}{50}$th of an inch in diameter, placed side by side, so as to form a scale of equal parts, which may be with ease counted by means of a certain regular variation of the lengths of the wires.

The external appearance of the whole instrument is that of a common telescope consisting of three tubes. The scale occupies the place of the object-glass, and the little lens is situated at the smaller end, with a pair of plain glasses sliding before it, between which the subject of examination is to be included. This part of the apparatus is shown separately in Fig. 23. It has a projection, with a perforation, through which a pin is inserted, to connect it with a screw represented at *b*, Fig. 22. This screw gives lateral motion to the object, so as to make it correspond with any particular part of the scale. The lens has also a small motion of adjustment, by means of the cap *c*, Fig. 22, which renders the view of the magnified object distinct.

Before the instrument is completed, it is necessary to determine with precision the indications of the scale, which must be different, according to the distance to which the tube is drawn out. In my instrument, one division of the scale corresponds to $\frac{1}{10000}$th of an inch, when it is at the distance of 16.6 inches from the lens; and since the apparent magnitude in small angles varies in the simple inverse ratio of this distance, each division of the same scale will correspond to $\frac{1}{5000}$th, at the distance of 8 $\frac{3}{10}$ inches, and the intermediate fractions $\frac{1}{6000}$, $\frac{1}{7000}$. &c. are found by intervals of

1.66 inch, marked on the outside of the tube. The basis on which these indications were founded in this instrument, was a wire, carefully ascertained to be $\frac{1}{20}$ of an inch in diameter, the magnified image of which occupied fifty divisions of the scale, when it was at the distance of 16.6 inches; and hence one division$=\frac{1}{50\times200}=\frac{1}{10000}$. Since any error in the original estimate of this wire must pervade all subsequent measures derived from it, the substance employed was pure gold, drawn till fifty two inches in length weighed exactly five grains. If we assume the specific gravity of gold to be 19.36, a cylindrical inch will weigh 3837 grains; and we may thence infer the diameter of such a wire to be $\frac{1}{200}$ of an inch, more nearly than can be ascertained by any other method.

For the sake of rendering the scale more accurate, a similar method was in fact pursued with several gold wires of different sizes, weighed with equal care; and the subdivisions of the exterior scale were made to correspond with the average of their indications.

In making use of this micrometer for taking the measure of any object, it would be sufficient, at any one accidental position of the tube, to note the number on the outside as denominator, and to observe the number of divisions and decimal parts which the subject of examination occupies on the interior scale as numerator of a fraction, expressing its dimensions in proportional parts of an inch; but it is preferable to obtain an integer as numerator by sliding the tube inward or outward, till the image of the wire is seen to correspond with some exact number of divisions, not only for the sake of greater simplicity in the arithmetical computations, but because we can by the eye judge more correctly of actual coincidence than of the conparative magnitudes of adjacent intervals. The smallest quantity which the graduations of this instrument profess to measure, is less than the eye can really appreciate in sliding the tube inward or outward. If, for instance, the object measured be really $\frac{1}{9900}$, it may appear $\frac{1}{10000}$, or $\frac{1}{9800}$, in which case the doubt amounts to $\frac{1}{50}$ part of the whole quantity. But the difference is here exceedingly small in comparison to the extreme division of other instruments where the nominal extent of its power is the same. A micrometer with a divided eye-glass, may profess to measure as far as $\frac{1}{10000}$ of an inch; but the next division is $\frac{2}{10000}$ or $\frac{1}{5000}$; and though the eye may be able to distinguish that the truth lies between the two, it receives no assistance within $\frac{1}{2}$ part of the larger measure."—*Phil. Trans.* 1813, p. 119.

In this ingenious instrument, where the variation of the scale is produced by placing the scale of wires at different distances from the observer, it is necessary that the scale be viewed by the naked eye, which by its adapting power can command distinct vision of it at different distances. We conceive, however, that it would be of advantage to have the scale at a permanent distance, and to view both the scale and the object to be measured with the aid of a lens, which may be easily done by placing a lens upon the small perforation. In this case it would be necessary to obtain a variation of the scale by means entirely different from those adopted by Dr. Wollaston.

A micrometer founded upon these principles has been proposed by Dr. Brewster, and may be easily constructed by a slight addition to a good kaleidoscope. Let ABC (Plate CCCLXXVI. Fig. 24.) be the aperture of the reflectors, and let *a b*, *d e* be the portion of a wire $\frac{1}{10}$th of an inch in diameter, that is seen directly through the aperture. When the wire is perpendicular to the reflector BC, its image *b c*, *e f* will coincide with the wire itself, and form an exact continuation of it. If we now turn round the cap till the wire comes into the position $a'\,b'$, $d'\,e'$, its reflected image $b'\,c'$, $e'\,f'$ will be inclined to the wire, and the thickness $b'\,e'$, or the oblique section of the wire, will be to its thicknes *b e* or $\frac{1}{10}$th of an inch as the secant of the arch (A) through which the wire has passed in going from the position *a b*, *d e* into the position $a'\,b'$, $d'\,e'$, is to 1, that is $b'\,e'=b\,e\times\sec.\,A=\frac{1}{10}\times\sec.\,A$. In this way the thickness of any wire may be made to vary and form a scale by which any other object may be measured by projecting against it, if it be very minute, and by juxta position if it is nearly of the same size. The unit of the scale, or *a b d e*, may be either a wire as already mentioned, or a luminous aperture, or the interval between two wires; and in order that the arch A may be always small, in which case the secants vary slowly, different units or standards may be fixed upon the cap of the instrument, which is divided into degrees for the purpose of measuring the arch A.

When the object is very minute, it must be placed in the focus of a magnifying lens, while the eye looks at the scale either through a perforation in that lens, if it has a considerable focal length, or at its side, if it has a small focal length. If the object is not microscopical, as ABCD, it may be measured by introducing it at the object end of the instrument, and having raised the standard scale *a m n d* till its oblique section *m n* is exactly equal to the diameter of the object ABCD. It is unnecessary to enter into any farther details respecting this instrument, as our only object at present is to explain the principle on which it is founded.

A similar instrument may be made by means of a doubly refracting plate placed at the upper end of a tube. A rectangular aperture is placed before this plate, of such a magnitude that its two images are exactly in contact when they are parallel to each other. By giving a rotatory motion of 90° to the rectangular aperture, the two apertures coincide in the direction of their length, and we have an arch of 90° to measure the variation. The breadth of the compound aperture will always be $A+A\sin.\,\phi$, A being the breadth of the rectangular aperture, and the ϕ arch described by the aperture reckoned from the longitudinal coincidence of the two images.

The principle of double refraction may be advantageously employed in the construction of a micrometer for measuring directly the magnitudes of objects of extreme minuteness. Let it be required, for example, to measure objects whose diameters are between the $\frac{1}{500}$th and $\frac{1}{5000}$th of an inch. Take a plate of rock crystal AB, CD (Plate CCCLXXVI. Fig. 25.) about two inches long, whose thickness AB at one end is ten times greater than its thickness CD at the other, and let the plate be cut out of the crystal, so that the two images of a wire $\frac{1}{500}$th of an inch in diameter will be in accurate contact, then at the other end CD, the two images of a wire $\frac{1}{5000}$th of an inch in diameter will be in accurate contact, and wires, or objects of all intermediate magnitudes, will be measured by observing the part of the scale between A and C, where their two images are in contact. This scale being two inches long may consist of a plate of mother-of-pearl attached to the rock crystal, and divided into 400 parts, so that each division will correspond to the $\frac{4500}{400}$, or a little more than $\frac{1}{1002}$dth parts of an inch. A prism of crown glass is cemented to the prism of rock crystal, in order to correct the dispersion, and a lens of high magnifying power is made to slide along it, in order to observe the coincidence of the images. The principle explained in the preceding paragraph may also be employed alone in plates of rock crystal, the object to be measured being substituted in place of the rectangular aperture. Or both these principles may be combined in one instrument.

MICROSCOPE.

Microscope, from μικρος, *small*, and σκοπεω, *to see*, is the name of a well known optical instrument, for seeing or magnifying minute objects.

The invention of the microscope, like that of the telescope, has been claimed for more than one individual.* Peter Borellus, in his work *De Vero Telescopii inventore*, published at the Hague in 1655, has adduced a good deal of evidence connected with the invention of the telescope and the microscope. He brings forward five different testimonies, and a letter from William Boreel, envoy from the States of Holland, which throw considerable light on the subject. Boreel was intimately acquainted with Zacharias Jansen, and had frequently been in his father's shop. He had often heard that the Jansens were the inventors of the microscope; and having been in England in 1619, he saw in the hands of his friend Cornelius Drebell, the very same microscope which Zacharius Jansen and his father had presented to Prince Maurice, and Albert, archduke of Austria. This instrument was six feet long, consisting of a tube of gilt copper, an inch in diameter, supported by thin brass pillars in the shape of dolphins, on a base of ebony, for the purpose of holding the objects to be examined. There is reason to think, that this was nothing more than a telescope converted into a compound microscope. Cornelius Drebell, therefore, who has commonly been considered as the inventor of the microscope, appears to have derived this honour from the accidental circumstance of his having exhibited the microscope made by Jansen; and as he was a favourite at the court of James VI. where he lived some time, this opinion may have proceeded, not only from his own arrogance, but from the influence of royal favour.

Viviani expressly informs us, in his life of Galileo, that this great man was led to the construction of the microscope from that of the telescope; and that, in the year 1612 he actually sent a microscope to Sigismund, King of Poland. Dissatisfied with the performance of this instrument, he appears, from his letters, to have been much occupied about 1624 in bringing it to perfection, but we have no information respecting the result of his labours.

As there is no reason to believe that the microscopes invented by Jansen consisted of two convex lenses, like those now in use, the honour of this improvement seems to be due to M. Fontana, a Neapolitan, who first described it in his work entitled *Novæ Terrestrium et Celestium Observationes, Neap.* 1646. Fontana distinctly assumes the merit of this improvement, and as no other person has laid claim to it, we agree with Montucla in allowing him the possession of this honour †

In pursuing this subject, we shall confine ourselves solely to the description of microscopes, supposing that the reader is acquainted with the principles of their construction, which fall to be explained under the article Optics. We shall treat, 1st, On Single Microscopes; 2dly, On Compound Microscopes; 3dly, On the Solar Microscope; 4thly, On the Lucernal Microscope; and, 5thly, On Microscopic Objects.

CHAP. I.

On Single Microscopes.

A *Single Microscope*, is an instrument in which only a single lens or mirror is employed for the purpose of magnifying objects. If the instrument is furnished with mirrors or lenses for illuminating the object, or with any other apparatus, however complicated, it still comes under the denomination of a single microscope.

One of the simplest of all single microscopes is a plano-convex, or a double convex lens of glass, fitted into a rim of brass furnished with a handle The object is then held in the interior focus of this lens, and appears magnified in proportion to the smallness of its focal length.

Microscopes of this kind were first successfully applied to the examination of natural objects by the celebrated Anthony Van Leewenhoek They consisted of a small double convex lens, carefully ground and polished, and inserted between two thin plates of metal, pierced with a hole smaller than the diameter of the lens, and afterwards rivetted The object was placed upon a silver point or needle, which, by the agency of screws, could be turned in all directions, and placed at any requisite distance from the lens. To this needle the objects were fixed with glue when they were solid; and when they were fluid, he put them on a thin film of mica, or brown glass, which was afterwards attached to the needle by glue In all Leewenhoek's microscopes the lenses had not a very high magnifying power; and there is reason to believe, that most of his discoveries were made more from the distinctness arising from the accurate figure and good polish of his lenses, than from the greatness of their power. Of the twenty-six microscopes which he presented to the Royal Society, only *one* had a focal length so small as $\frac{1}{20}$th of an inch, and all the rest were below *half an inch* in focal length.

Dr Hooke appears to have been the first who substituted glass globules in place of convex lenses. In

* It seems to be quite certain that the ancients were acquainted with the use of the single microscope, at least in one of its forms, as appears from the following passage in Seneca, *Literæ, quamvis minutæ et obscuræ, per vitream pilam aqua plenam, majores clarioresque cernuntur.* "Letters, though minute and obscure, appear larger and clearer through a glass bubble filled with water." *Nat Quest.* lib. i. cap 7.

† Doctor Priestley has completely misunderstood Montucla's observations on this subject, when he represents him as ascribing to Fontana the invention of compound microscopes. See Montucla's *Hist. des Math.* tom. ii. p. 239; and Priestley *On Vision*, vol. i. p. 78.

the preface to his *Micrographia*, published in 1665, he describes the method of making them. A small rod or strip of thin and good window glass is drawn out into fine threads, either by holding it in the flame of a candle, or a lamp with spirit of wine or good oil. The end of one of these threads is then held in the flame till it runs into a small drop or globule of the required size. When the globule has cooled, it is fixed upon a thin plate of brass or silver, so that the centre of it is directly over the centre of a very small hole in the metallic plate. In this way, none of the rays of light that issue from an object placed in its focus pass through the part of the globule where it is joined to the glass thread. Dr. Hooke also fixed the globules with sealing wax to the end of a stick, so that the threads stood upwards, and he ground off the ends of the threads, and polished them.

The art of making microscopic globules of glass was brought to great perfection by Father di Torre of Naples. Having formed glass globules by the method already described, he separated the ball of glass from the thread by the sharp edge of a piece of flint. When a great number of globules were made in this manner, he next proceeded to give them a complete spherical form, by melting them a second time. For this purpose, he made use of a piece of tripoli about four or five inches long, and three or four inches thick. After it had been calcined, by surrounding it with charcoal nearly red hot, and allowed to grow quite cold, several small hemispherical cavities of different diameters are made on the flat side of it, and are nicely polished and neatly rounded at the edge. The small glass globules, after being carefully cleaned, are placed in the cavities of the tripoli by a pair of delicate nippers. The extremity of the flame of a blow-pipe is then directed towards the globules, which assume a perfectly spherical form when brought to a fluid state, and never adhere to the tripoli. When the globule is cold, it is cleaned by rubbing it between two pieces of paper, and is then set in a brass cap for the purpose of trying its figure, by viewing an object through it. It sometimes happened, that in damp weather only *four* or *five* globules out of forty were fit for use. In the year 1761, four of Father di Torre's microscopes were sent in a present to the Royal Society. One of them had a diameter of $\frac{1}{36}$th of an inch, two of them a diameter of $\frac{1}{72}$d part of an inch, and the fourth a diameter of only the $\frac{1}{144}$th of an inch. Mr. Baker, who examined these globules with great care, could not make use of the smallest of them, and considered them as more curious than useful.

Another method of making glass globules, was described by Mr. Butterfield in the *Phil Trans.* for 1678. He used the flame of spirit of wine, well rectified, and burned in a lamp; but instead of cotton he employed small silver wire, doubled up and down like a skein of thread, which being wet with the spirit of wine, and made to burn in the lamp, gives a very ardent flame. Having pounded some glass, and washed it very clean, take some of it up on the point of a silver needle filed very small, and wetted. It must then be held in the flame till it be quite round, and no longer; and if the side of the glass next the needle is not melted, it may be put off, and taken up with the wetted needle on the round side, presenting the rough side to the flame till it be every where very round and smooth. When wiped with a piece of soft leather, they are ready for being placed between two plates of metal for use.

The ingenious Mr. Stephen Gray proposed to construct single microscopes with drops of water, in the following manner: "I take a thin piece of brass," says he, "filing it into the form A B, (Plate CCCLXXVII. Fig. 1,) making a small hole at A, which serves for an aperture; then holding it by the other end B, I pour a few drops of water on the table, taking up a small globule thereof with a pin, which I lay on the hole A; then removing the pin, the water will remain on the aperture, in form of a hemisphere, or a plano-convex lens. But if I have a mind to make a double convex of water, I thrust the pin, which must be less than the hole, through the hole, till the water be entered therein; then, by drawing the pin perpendicularly to the plane of the aperture, the water remains there in form of an aqueous double convex lens. Then, whatever I have a mind to view I take upon a pin, or a piece of glass, according to the nature of the object; and taking up this natural microscope by the end B, I move the object to and fro, till it be in its focus; by which means I can see objects little less distinctly than by glass microscopes, especially by candle, which I find much better than by day-light.

"But I observed, that those irregular particles which are inherent in the globules of glass were seen distinctly, and prodigiously magnified, as was easy to imagine, both from their nearness to the eye, and because they did not hinder the globules, either by day or candle light, from appearing throughout transparent, being so minute as not to be discernible, except held close to the eye, as in time of observation, and not then neither, if too near the light, but at a competent distance, they appeared as above. I knew not well how at that time to account for this strange phenomenon, that an object should be placed so far within the focus of a sphericle, as to be within the glass, and yet seen distinctly to the eye so near it; but since, by matter of fact, I found it was so, I made this inference, and concluded, that if I conveyed a small globule of water to my eye, and that there were any opaceous, or less transparent particles than the water therein, I might see them distinctly.

"Having by me a small bottle of water, which I knew to have in it some of those minute insects which Mr. Leewenhoek discovered by the help of excellent microscopes; having seen them with the common glass microscopes, and with the first aqueous, as above mentioned, I poured a few drops of this water on the table, and taking a small portion of it on a pin, I laid it on the end of a small piece of brass-wire. I continued to lay on two or three portions of water, till there was formed somewhat more than a hemispherical of water; then, keeping the wire erect, I applied it to my eye, and standing at a proper distance from the light, I saw them, and some other irregular particles, most enormously magnified; for whereas they are scarcely discernible by the glass microscopes, or the first aqueous one, within the globule they appeared not much different both in their form, nor less in magnitude than ordinary peas. They cannot well be seen by day-light, except the room be darkened, after the manner of the famous dioptrical experiment, but most distinctly by candle-light; they may be very well seen by the full moon-light. The pin sometimes takes up the water round enough to show its objects distinct." This microscope is shewn fitted up in Plate CCCLXXVII. Fig. 3.

In order to explain the magnifying effect of the globe of water upon the animalcules, or other objects placed in the inside of it, he supposes "the circle in Fig. 2, to represent a sphere of water; A an object placed in its focus, sending forth a cone of rays, two of which are AB, AB, which, coming into the water at B and B, will be refracted from their direct course, and become BD. At D they will, at their passing into the air, be again refracted into DE, DE, and so run parallel to each other, and to the axis of the sphere AECG. Now, as the angle of reflection is equal to the angle of incidence, let the rays BD, BD, be imagined to come from some point of an object placed within a sphere of water, by being reflected from the interior surface of the sphere at BB; CBD is the angle of reflection, to which making CBF equal, so will F be the place where an object, sending forth a cone of rays, two of which are FB, FB, which are reflected into the rays BD, BD, and then coming to the other side of the sphere at D and D, they are refracted into DE, DE, as before, and consequently be as fit for distinct vision, whether the object be placed at F within, or in A without, the sphere of its interior surface be considered as a concave reflecting speculum." *Phil. Trans.* 1696, No. 221, p. 280.

This microscope is evidently one which operates both by reflection and refraction. The anterior part is a concave mirror, by which all objects placed between its surface and its focus are magnified; and, as Dr. Smith has shewn, it magnifies objects $3\frac{1}{3}$ times more than if they were presented to it in the usual manner. See Smith's *Optics*, Vol. II. p. 395.

Mr. Gray suggested also a single reflecting microscope, founded on a similar principle. Let A, (Plate CCCLXXVII. Fig. 4.) represent a small flat ring of brass, whose mean diameter does not exceed $\frac{4}{10}$ths of an inch, and which is about $\frac{1}{30}$th of an inch thick. Take a small globule of quicksilver, and dissolve it in a few drops of aquafortis, to which add 10 parts of common water; dip the end of a stick in this liquor, and rub with it the inner circle of the ring A, so as to give it a mercurial tincture. After it is wiped dry, and laid upon the table, pour a drop of quicksilver within it, which being pressed gently with the ball of the finger, will adhere to the ring; and when it is cleansed with a hare's foot, it will form a convex speculum. Take up the ring and speculum, carrying it horizontal, and lay it on the brims of the hollow cylinder B, and the mercury will now become a concave reflecting speculum, which may be used as a reflecting microscope. *Phil. Trans.* 1697, No. 228, p. 539.

Single microscopes, of a very simple kind, were constructed by Dr. Brewster, by taking up drops of very pure turpentine varnish, and allowing them to fall on a plate of thin and parallel glass. In this way he formed plano-convex lenses of any focal length; and, by dropping the varnish on both sides, he formed double convex lenses, with their convexities in any required ratio. The focal length of these lenses increase a little after they are formed, on the upper side of the glass, but diminish if they are formed on the lower side of it; and if they are preserved from dust, they will last a long time. Dr. Brewster employed these fluid lenses as the object glasses of compound microscopes.

A very ingenious method of forming single microscopes of glass has been recently proposed and executed by Mr. Sivright of Meggetland. Take a piece of platinum leaf, about the thickness of tinfoil, and make two or three circular holes in it, from one-twentieth to one-tenth of an inch in diameter, and at the distance of about half an inch from each other. In the holes put pieces of glass, which will stick in them without falling through, and which are thick enough to fill the apertures. When the glass is melted at the flame of a candle with the blow-pipe, it forms a lens which adheres strongly to the metal, and the lens is therefore formed and set at the same time. The pieces of glass used for this purpose should have no mark of a diamond or file upon them, as the mark always remains, however strongly they are heated with the blow-pipe. The lenses which were made larger than one-tenth of an inch were not so good as the rest, and the best were even of a smaller size than one-tenth. As the lenses thus formed sometimes contain air bubbles, the best way is to make several, and to select those which are freest from imperfections. An eye or loop, made by bending the extremity of a platinum wire, may be used instead of the platinum leaf. The reason of using platinum is, that the glass is more easily and more perfectly melted in this than in other metals, which may perhaps arise from its being a bad conductor of heat, and from its preserving its brightness. As platinum does not oxidate, the glass adheres better to the edges of the holes, and it may be used very thin, as it does not melt with the heat necessary for the complete fusion of the glass.

Mr. Sivright has likewise succeeded in forming plano-convex lenses by means of fusion. Having laid a fragment of glass upon a flat and perfectly polished natural surface of topaz, which is easily obtained by cleavage, he exposes the whole to an intense heat. The upper surface of the glass assumes a spherical figure, in virtue of the mutual attraction of its parts, and the lower surface becomes perfectly flat, and highly polished, from its contact with the polished plate of topaz. See *Edinburgh Philosoph. Journal*, vol. I. p. 81.

A new kind of single microscopes, which possess particular properties, have been lately constructed by Dr. Brewster. They consist of plano-convex or double-convex lenses of a hemispherical or spherical form, which may be converted into single microscopes, having a much greater magnifying power than when they are used in the ordinary way. Let ABC, (Plate CCCLXXVII. Fig. 5.) for example, be a hemispherical plano-convex lens, which may be used as a single microscope, either by presenting the side A or the side D to the object. But if we place the object at *mn*, and looking in at F, examine it after reflexion from the surface BC, we shall have an effect the same as if we had placed the two lenses A *a* B *d*, A *a c d*, with their plane sides AB, AC together, or rather of a double-convex lens similar to the two united. As the light is incident on BDC at an angle of 45°, it will suffer total reflexion, and not a ray of it will be lost. The spherical aberration of the lens used in this way, is to its spherical aberration used in the common way, as 97 to 117. A hemispherical lens employed in this manner, and having the line BC inclined 45° to the axis of telescope, will form the best possible diagonal eye-piece. When the segment ABC is less or greater than a hemisphere, the same effects will be produced. With a double-convex lens, as shewn in Plate CCCLXXVII. Fig. 6. a very high degree of magnifying power is obtained by looking in at E, and we have the effect of a compound microscope, consisting of an object-lens AC, a concave mirror CBD, and an eye-glass AC. The perfection of the image will, in this case, increase, as the incident or reflected rays approach to DA. In these, as well as in all other microscopes, the object should be illuminated from one point, such as a single candle or luminous aperture. See the *Edinburgh Philosophical Journal*, No. V.

A very great improvement on the microscope has been lately suggested by Dr. Wollaston, under the name of the Periscopic Microscope.

"The great desideratum," says he, "in employing high magnifiers, is sufficiency of light; and it is accordingly expedient to make the aperture of the little lens as large as is consistent with distinct vision. But if the object to be viewed is of such magnitude as to appear under an angle of several degrees on each side of the centre, the requisite distinctness cannot be given to the whole surface by a common lens, in consequence of the confusion occasioned by oblique incidence of the lateral rays, excepting by means of a very small aperture, and proportionable diminution of light. In order to remedy this inconvenience, I conceived that the perforated metal which limits the aperture of the lens might be placed with advantage in its centre, and accordingly I procured two plano-convex lenses, ground to the same radius, and applying their plane surface on opposite sides of the same aperture, in a thin piece of metal, (as is represented by a section, Plate CCCLXXVII. Fig. 7,) I produced the desired effect; having virtually a double-convex lens, so contrived that the passage of oblique pencils was at right angles with its surface, as well as the central pencil. With a lens so constructed, perforation that appeared to give the most perfect distinctness was about one-fifth part of the focal length in diameter; and when such an aperture is well centered, the visible field is at least as much as 20 degrees in diameter. It is true that a portion of light is lost by doubling the number of surfaces; but this is more than compensated by the greater aperture which, under these circumstances, is compatible with distinct vision." *Phil. Trans.* 1812, p. 375.

It is obvious from the last paragraph of this quotation, tbat the idea had not occurred to Dr. Wollaston of filling up the central aperture with a fluid of the same refractive power as the glass of which the two lenses are composed. This improvement, which was practised by Dr. Brewster, (as shewn in Plate CCCLXXVII. Fig. 8.) removes entirely the loss of light arising from doubling the surfaces. The same thing may be done in a still more perfect manner, as in Fig. 9. as proposed by the same author, where a groove is cut round the globule or spherical lens, by the wheel of a seal engraver. By this means the doubling of the surfaces is avoided, and the most perfect centering obtained. As it is much more easy to grind two double convex lenses, than two plano-convex ones, as shewn in Fig. 7. we might avail ourselves of this circumstance in the construction, to adopt the form shewn in Fig. 10. and render the microscope achromatic, by introducing a concave fluid lens of a different refractive and dispersive power, as shewn in Fig. 10. which, independent of the correction of colour, is a simpler construction than that shewn in Fig. 7.

Following out the principles which we have here explained, Dr. Brewster has proposed a miscroscope, constructed as in Plate CCCLXXVII. Fig. 11. where AB, CD, are two double convex lenses, so constructed that the concave lenticular space ABDC, would, when filled with a fluid of different dispersive and refractive power, correct the aberration of refrangibility. A convex speculum of steel or polished silver, perforated with an aperture *c f*, has its anterior surface P *e* Q highly polished, and either attached by a transparent cement or not to the lens AB. The aperture *e f* being filled with the proper fluid, and CD cemented to the posterior part of the steel, the lens is ready for use. The curvature of the reflector P *e* Q, is such as to reflect parallel rays incident on AB, upon the object to be examined, being converted into a concave speculum by the lens placed before it.

By this means, we obtain a lens possessing very unusual properties, and capable of affording the most perfect view of microscopic objects.*

Having thus described the various kinds of single microscopes which have been used, we shall now give an account of the improvements which have been made in adapting them to the examination of minute objects.

The first and most important of these improvements was made about the year 1739, by Dr. Lieberkhun. He placed the single lens on the centre of a convex speculum, made of silver, and highly polished, and having its concavity so adjusted to the focal length of the lens, that the light of a candle or of the sky could be thrown upon the side of the object next the observer. When the single lens is of a small focal length, the light is kept from falling upon the object, not only by its proximity to the lens, but by the body of the observer, so that it becomes impossible to examine microscopic objects, particularly opaque ones, with any satisfaction. Dr. Lieberkhun adapted a microscope to every object of any particular interest. At the eye end of a short brass tube, he placed the convave speculum, carrying the single lens in its centre. The object was placed in the middle of the tube, and had a contrivance for adjusting it to distinct vision, and at the object end of the tube, there was a plano-convex lens for concentrating the light which fell upon the concave speculum. Some of these microscopes are said to be deposited in the British Museum.

We shall now proceed to descibe some of the best single microscopes, as fitted up for use. The most important of these are:

1. The common flower and insect microscope.
2. The small microscope, with apparatus for opaque objects.
3. Withering's botanical microscope.
4. The pocket botanical and universal microscope.
5. Lyonet's anatomical microscope.
9. Wilson's pocket microscope.
7. Ellis's aquatic microscope.
8. Barrel microscope.

I. *Description of the Common Flower and Insect Microscope.*

This microscope is one of the most simple, and the most convenient, and is peculiarly fitted for being put into the hands of young persons, who are not capable of managing a more complicated apparatus. Above

* See the *Edinburgh Philosophical Journal*, No. V. or Vol. III. Part I.

the handle H, (Plate CCCLXXVII. Fig. 12) is fixed the arm LM, which carries a lens at L, which may be either used alone, when a small power is wanted, or in conjunction with another lens *a*, which screws on the ring at L, when a higher power is needed. A horizontal grooved arm MN, also fixed to the handle, carries the pincers or forceps OP, which hold the object O, and this object can be placed at different distances from the lens L, so as to obtain distinct vision by sliding the forceps along the groove in MN, and fixing it at the proper position by means of the button or nut B.

II. *Description of the Microscope for Opaque Objects.*

This microscope, which is a little more complicated than the preceding, is represented in Plate CCCLXXVII. Fig. 13. The ivory handle P is fixed in the arm A, through which passes a screw B, having its other end fastened to the moveable arm C. By turning the nut D upon the head of the screw B, the arms A and C may be either separated or brought together, being kept asunder by a steel spring E. The piece GH, consisting of a pointed steel wire G, and of a pair of pliers H, passes through a spring socket moving on a rivet. The object may be either fixed on the point G, or taken up by the pliers, and may be turned round in any direction, by the joint at F, or by sliding the piece GH through the spring socket. A ring of brass I with a female screw is fixed on an upright piece of brass turning on a pivot, in order that it may be set at a proper distance when the smallest magnifiers are employed. A concave speculum K, of polished silver, has a lens placed in its centre, according to the method of Dr. Lieberkhun, already described; and there are generally four of these of different concavities, with four glasses of different magnifying powers. A round object-plate, as shown at M, has one side white and the other black, all dark objects being placed upon the white side, and all light objects upon the black side, in order to render them more visible by contrast. A steel spring N, moving round the centre, can be turned down on each side, for the purpose of pressing the object to the black or white ground. A hollow pipe proceeds from the object-plate, in order to screw it on the point of the needle G. A small box O of brass, with a glass on each side, for the purpose of enclosing any living object for examination, has likewise a pipe for the purpose of screwing it upon the end of the needle FG. A pair of pliers for taking up any object is shown at Q, and a soft hair brush at R.

In using this microscope, the speculum KL, with its accompanying magnifier, must be screwed into the ring I. The object is then to be placed according to its nature on the needle G, in the pliers H, or on the black or white side of the object-plate M, or between the glass plates of the box O; and having taken the instrument by the handle P, the eye looks through the magnifying lens screwed on at I, and by means of the nut D, and the motion of the needle, the object may be turned about, raised or depressed, or made to approach to or recede from the lens, till it is placed in the true anterior focus of the lens, where the light will be reflected upon it by the concave speculum.

III. *Withering's Botanical Microscope.*

The botanical microscope used by Dr. Withering, is shown in Plate CCCLXXVII. Fig. 14. where A, B, C, are three parallel brass plates. Two wires D and E are rivetted into the upper and lower plates A and C, and the middle plate B is moveable along these wires by two little sockets fixed to it. The two upper plates contain each a magnifying lens of different focal lengths, one of which keeps in their places the sharp point F, the small knife K, and the pliers P.

Before using this microscope, we must unscrew the upper lens, and take out the point, the knife, and the pliers; and having replaced the lens by screwing it on again, the object is placed on the stage, and moved up or down till it is seen distinctly.

IV. *Pocket Botanical and Universal Microscope.*

This instrument, which is superior to Dr. Withering's, is represented in Plate CCCLXXVII. Fig. 15. A small arm AB carries three lenses, two of which are fixed to the upper part at B, and the other to the lower part at C; and as these three lenses may be either used separately or combined, they afford us seven different magnifying powers. A square pillar AK supports the arm AB. The lower end of this pillar fits into the socket E of the base FG. The stage DL, carrying the pliers M and a sharp point N, constructed as formerly described, is made to slide up and down the pillar IK. A reflecting mirror H, moving round a horizontal and vertical axis, is fixed into the base FG, and reflects light through the object. In using this microscope, the objects are placed on the stage L; or, if they are put into ivory sliders, these sliders pass under the stage L. The light is then thrown upon the object by the mirror H, and distinct vision obtained by the motion of the stage. Other objects may be fixed in the pliers M, N, and used as already described.

The apparatus accompanying this instrument consists of three ivory sliders, a pair of nippers, a flat glass, and a concave lens, all of which are fitted to the stage L. By taking out the pin E, the pillar IK may be turned half round, and the base FG used as a handle. The stage DL, instead of being moved by the hand, is frequently raised and depressed by an adjusting screw.

V. *Lyonet's Anatomical Microscope.*

The microscope represented in Plate CCCLXXVII. Fig. 16, was employed by M. Lyonet in his microscopical dissection of the caterpillar of the goat moth. It consists of an anatomical table AB, supported by a pillar ON, screwed into the mahogany box DC. In the table AB, which is prevented from turning round by two steady pins, is an aperture G, exactly over the mirror EF, for reflecting light on the object. A flat or concave glass is placed on the aperture G. for receiving the objects to be dissected. An arm RXZ, composed of several balls and sockets, by which it has an universal motion, is fixed to the table AB by means of the screw H. The last arm IZ carries a female screw for receiving a magnifying lens, as shown at Z. The lens is generally adjusted to distinct vision of the object by the hand, though a small motion may be given to it by the screw at H. Another chain of balls and sockets is sometimes used for holding an illuminating lens. The mirror EF can also be taken from its place at K, and fixed by a clamp to any part of the table AB.

In using the dissecting table, the instrument should stand upon a firm table, the left side of the observer being near a light window, and the side DL towards his breast. The observations should be made with the left eye; and in dissecting, the two elbows should be supported on the table which holds the microscope, the hands resting against the board AB, to give it greater steadiness. See Lyonet's *Traité Anatomique de la Chenille, &c.*

VI. *Wilson's Pocket Microscope.*

The microscope invented by Mr. Wilson has been long in use. The body of it is represented by AB, (Plate CCCLXXVII. Fig. 17.) and is made either of brass, silver, or ivory. Another tube, with a long fine-threaded small screw upon its circumference, screws unto the body AB. A convex lens D is screwed into the end of the tube CC, and its area may be increased or diminished by placing upon it one or other of the two concave apertures of thin brass, which are necessary when the highest magnifiers are employed. Two thin plates of brass are shown at E, within the body of the microscope; and one of them is bent into an arched or semicylindrical cavity, shown in the figure, for the purpose of receiving a tube of glass. At the eye-end G of the microscope is a female screw for receiving the different magnifiers. A spiral steel spring H, abutting with one extremity against the end G and with the other against the plate of brass E, serves to keep the plates in a proper position, and to act against the long screw C. The microscope is held by the ivory handle I. *Seven* different magnifying glasses, *six* of which are set in cells, as shown at K, are numbered from 1 to 6, the least numbers being the highest magnifiers. The *seventh*, or least magnifier, is set in a small tube, in order that it may be held in the hand for viewing any large object. The objects are held in an ivory slider M. Six sliders like this of ivory, and one of brass, generally accompanying the instrument. A brass slider, not represented in the figure, is sometimes added, for the purpose of confining any small object, in order that it may be examined without being crushed. A pair of forceps and a hair-brush are used, as shown at R and Q, Fig. 13. A glass tube, for holding living objects, such as frogs, fishes, &c. is shown at P.

In order to use this microscope, the slider containing the object is thrust between the two flat brass plates EF, care being taken to put the face of the slider where the brass rings are farthest from the eye. The magnifying glass intended for use must then be screwed on at G; and while the eye looks through it against the sky, or the light employed, the long screw CC is turned till the objects in the slider are brought into the anterior focus of the lens, when a distinct view of them will be obtained. By moving the sliders between the plates at E, different parts of the same object may be brought into view, or different objects in the slider; but at every motion of the slider, vision should be made distinct by a new adjustment with the screw.

This instrument is sometimes placed upon a stand, with a reflecting mirror, as shown in Fig. 15. In order to see opaque objects with it in this case, an arm QR, Fig. 17. is screwed into the body of the microscope at G. The proper magnifier is next screwed into the hole at R, and putting the concave speculum S on the outside of the ring R, the object is held upon the forceps, or point of T, whose wire slips into a small hole, shown at *u*, in the body of the microscope. The arm R is then turned till the magnifier is brought over the object, and distinct vision is obtained by turning the screw C as formerly.

VII. *Ellis's Aquatic Microscope.*

This microscope differs from the one shown in Fig. 15 so little, that it is unnecessary to engrave it. Instead of the stage DL moving, the arm AB containing the magnifiers slides up and down. The magnifiers are each set in the centre of a concave silver speculum. This microscope was employed by Ellis in his observations on Corallines and the Zoophytes. See Ellis's *Essay on the Natural History of Corallines*, and his *Natural History of many curious and uncommon Zoophytes.*

VIII. *Barrelled Microscopes.*

Single microscopes for opaque objects are sometimes conveniently fitted up with a barrel or cylinder, on the circumference of which are placed the objects to be examined. By turning the barrel round its axis, the different objects are brought under the magnifiers, and by a lateral motion of the barrel, other objects may be brought into view.

IX. *On the magnifying power of Single Microscopes.*

The magnifying power of single microscopes increases with the smallness of their focal length, and may be easily found, by dividing the distance at which the eye sees objects distinctly by the focal length of the lens or globule. This distance varies in different persons, and has generally been assumed at 7 or 8 inches. It is obvious, however, that very minute microscopic objects, when examined with an eye of the ordinary focal length, are always viewed at a less distance than 7 or 8 inches, in order to obtain the best possible view of them; and, therefore, it is this distance that should be divided by the focal length, in order to obtain the magnifying power of the instrument, or the real measure of the help which we derive from it. This distance will be found not to exceed *five inches*; and upon this supposition we have computed the following Table, shewing the magnifying power of single microscopes from $\frac{1}{100}$th of an inch to 1 inch.

Table of the Magnifying Power of Small Convex Lenses, or Single Microscopes, the Distance at which the Eye sees distinctly being 5 Inches.

Focal Distance of the Lens, or Microscope.		Number of Times, that the *Diameter* of an Object is magnified.	Number of Times that the *Surface* of an Object is magnified.	Number of Times that the *Cube* of an Object is magnified.
100dths of an Inch.		Times. Dec. of a Time.	Times.	Times.
1	100	5.00	25	125
$\frac{3}{4}$	75	6.67	44	297
$\frac{1}{2}$	50	10.00	100	1000
$\frac{2}{5}$	40	12 50	156	1953
$\frac{3}{10}$	30	16.67	278	4632
$\frac{2}{10}$	20	25.00	625	15625
	19	26.32	693	18233
	18	27.78	772	21439
	17	29 41	865	25438
	16	31.25	977	30510
	15	33.33	1111	37026
	14	35.71	1275	43538
	13	38.48	1481	56978
	12	41.67	1736	72355
	11	45 55	2075	94507
$\frac{1}{10}$	10	50.00	2500	125000
	9	55 55	3086	171416
	8	62 50	3906	244141
	7	71.43	5102	364453
	6	83.33	6944	578634
$\frac{1}{20}$	5	100.00	10000	1000000
$\frac{1}{25}$	4	125.00	15625	1953125
	3	166.67	27779	4629907
$\frac{1}{50}$	2	250.00	62500	15625000
	1	500 00	250000	125000000

The *first* column of the Table shows the focal length of the lens, or globule, in 100dths of an inch. The *second* column shows the number of times that it is magnified in diameter, or in one dimension. The *third* column shows the number of times that the surface is magnified; and the *fourth*, the number of times that the cube of an object is magnified.

As microscopic objects, however, are never mathematical lines, and as their solidity, or their magnitude in three dimensions, cannot be rendered visible by a microscope, we consider the *second* column as containing the *real magnifying power of the microscope*, although opticians have hitherto adopted the numbers in the first column, from an erroneous analogy with the telescope.

CHAP. II.

On Compound Microscopes.

We have no means of ascertaining, from the descriptions of Jansen's microscope, the particular combination of lenses which he employed. It seems more than probable, that the microscopes used by him and Galileo consisted of a convex object lens, and a concave eye-glass, and were nothing more than a short telescope converted into a microscope by lengthening its tube.

In 1646, Fontana tried two convex lenses; and in all the microscopes which were subsequently used, three or more convex lenses were employed, as in the finest instruments which are now in use. Dr. Hooke, in the Preface to his *Micographia*, gives an account of the microscope which he employed. It was about seven inches long, and three inches in diameter, and consisted of four drawing tubes, by which it could be lengthened or shortened at pleasure. It had three glasses, viz. a small object-glass, a middle glass, and an eye-glass. When he wished to have a large field, or to see a great part of the object an once, he used all the three lenses—the middle lense converging upon the eye-glass pencils, which, by their divergency, could not have fallen upon it. But when he wished to examine any individual part with the greatest distinctness, he removed the middle glass, and used only the other two glasses.

A description of the microscope of Eustachio Divini, was laid before the Royal Society in 1668. It consisted of an object-glass, a middle-glass, and *two eye-glasses*, which are plano-convex, and placed so as to touch one another in the middle of the convex surfaces. The purpose of his construction was to shew the objects flat, and not crooked, and to take in a large field, at the same time that it had a high magnifying power. It was about $16\frac{1}{2}$ inches high, and adjusted at four different lengths. In the first, which is the best, it shews lines 41 times larger than they appear to the naked eye; in the second, 90 times; in the third, 111 times; and in the fourth, 143 times. The diameter of the field, or the subtense of the visual angle, measured upon the object plate, in the *first* length, was 8 inches 7 lines; in the *second*, 12 inches 4 lines; in the *third*, 13 inches; and in the *fourth*, a little more than 16 inches. The tube was as large as a man's leg, and the eye-glasses like the palm of the hand. See *Phil. Trans.* 1668. No. 42. p. 842.

Philip Bonnani, in a work entitled *Observationes circa Viventia, quæ in rebus non viventibus reperiuntur, &c.* 1791, published an account of two compound microscopes which he used. One of these was composed of an eye-glass, a middle-glass, and an object-glass, mounted in a cylindrical tube placed horizontally. Behind the stage was a small tube, with a convex lens at each end, and a lamp beyond it, whose light was concentrated by the lenses in the tube, and thrown upon the object to be examined. The instrument possessed various adjustments, and was regulated by a rack and pinion.

Sir Isaac Newton seems to have been the first person who suggested the use of a reflecting microscope. He placed the objects before a concave speculum, so that an enlarged image of them was formed at a greater distance. This image being viewed with a convex eye-glass, was again magnified, and appeared very distinct. The great defect of this instrument arose from its being inapplicable to opaque objects, in consequence of the objects being placed between the object speculum and the eye-glass. See *Phil. Trans.* 1672, No. 10. p. 3075, and the Appendix to Gregory's *Elements of Optics*.

Another form of the reflecting microscope was suggested by Dr. Robert Barker, in the year 1736. It was nothing more than the Gregorian telescope converted into a microscope, merely by lengthing the tube, and therefore requires no particular description. There can be no doubt that it would give very distinct images, and has the advantage of allowing the light to fall freely upon the object, which is placed at a distance of from 9 to 24 inches beyond the tube. See *Phil. Trans.* 1736, Vol. 39. No. 442. p. 259.

The next compound microscope was invented by Dr.

Robert Smith, Professor of Experimental philosophy at Cambridge. Having had occasion to examine the principles of Sir Isaac Newton's reflecting microscope, he constructed one of them, in which the focal distance of the speculum was $2\frac{1}{3}$ inches. He "found that the colours of objects appeared much more beautiful and natural than in doubly refracting microscopes of the best sort, their proper colours being free from the mixture of other colours arising in refracting microscopes, from the different refrangibility of rays." Smith's *Optics*, Vol. I. p. 279. He found also that objects appeared sufficiently bright, and very distinct, when the reflecting microscope had the following dimensions:

Focal length of the speculum . .	$2\frac{1}{3}$ inches.
Diameter of the speculum . . .	1
Focal length of the plano-convex eye-glass	$2\frac{1}{3}$
Ratio of the distance of the object from the focus of the speculum, to the focal distance of the speculum . . .	1 to 14

Having found that, in order to produce a high magnifying power with this reflecting microscope, it was necessary to have the speculum very concave, and therefore very small, he set about contriving a microscope with two reflecting spherical surfaces of any size, so proportioned to each other that the aberration of the rays, caused by the first reflection, should be perfectly corrected by the second, and, consequently, that the last image of the object from which the rays diverge upon the eye-glass, shall be perfectly free from aberration.

One of Dr. Smith's microscopes is shewn in Plate CCCLXXVII. Fig. 18. where AA is a concave spherical speculum, and CC a convex spherical speculum, having its polished convex surface inwards. The rays from an object *o* placed in the slider *mn*, will be reflected from the concave speculum AA upon the concave CC, and will have a distinct and magnified image of it formed before the convex eye-glass E, by which it will be magnified still more. This instrument, in short, is nothing more than the Cassegrainian telescope converted into a microscope, with this difference only, that, in the telescope, distinct vision is obtained by moving the convex mirror, whereas, in the microscope, it is obtained by a motion of the eye-glass. Dr. Smith constructed one of these microscopes, which he found to perform "nearly as well, in all respects, as the very best refracting microscopes;" and the writer of this article has one of them now before him, which performs wonderfully well, though both the specula have their polish considerably injured. The following are the dimensions, &c. of Dr. Smith's reflecting microscope as given by himself:

Focal length of both specula . .	1 0000
Distance of the centres of both specula	1.6558
Distance of the image from the centre of the concave speculum . .	1.1337
Focal length of the eye-glass . .	.0.1407
Distance of the eye behind the eye-glass	0.1479
Diameter of the eye-hole . . .	0.0190
Distance of the object from the centre of the convex speculum . .	0.0626
Length of the concave speculum .	15° 47
Arch of the convex speculum . .	4° 50′ 49″
Distance of the stop *s* from the object	0.4545
Diameter of the stop *s* . . .	0.038
Diameter of the hole in the concave speculum	0.143
Diameter of the hole in the convex speculum	0 049
Magnifying power, the focal length, &c. of the eye being 8 inches . . .	300 times.

The stop *s* is placed behind the convex speculum, in order to prevent the direct rays from the object, which would pass unreflected through the openings in both specula, and fall upon the eye-glass, from mixing with the rays regularly reflected by the specula, and forming the magnified image upon the retina. See Smith's *Optics*, Vol. II. Remarks, p. 94.

The next microscopes which excited any notice, were those of M. Delebarre of the Hague, who began to construct them in 1771. Montucla saw them when he travelled in Holland in 1773, and induced Delebarre to go to Paris, where he was well received, and where he sold many of his instruments, each of which cost about 15*l*.* M. M. Montigny, Leroi, and Brisson, submitted to the Academy, on the 21st of June, 1777, a most flattering report of their performance, and Montucla has given a very full account of them in his History of Mathematics. We have read these eulogiums and descriptions with great attention, and are obliged to acknowledge, that we cannot find in the microscope of Delebarre any improvement of the least importance which had not been known and adopted by the London opticians. The only point of difference that we can observe is, that of changing the eye-glasses, and of combining six lenses at once, which Montucla seems to lay considerable stress upon, because Euler, in his paper *De Novo Microscopiorum genere*, published in the memoirs of St. Petersburgh for 1766 and 1767, had pointed out certain theoretical advantages which he conceived would be found in microscopes with six lenses. Such a combination of lenses, however, has been exploded, and we do not scruple to say, that there is no eminent optician in Europe who would construct a microscope in such a manner, unless the lenses were arranged, as in some modern eye-pieces, so as to correct the chromatic aberration.

M. Æpinus of St. Petersburgh proposed in the year 1784, (*Nov. Act. Petrop.* 1784,) to construct microscopes with large apertures of considerable length, *with Achromatic object-glasses*. The great object of this construction was to permit light to be easily thrown upon the object; and in order to put his idea to the test of experiment, he constructed a microscope, in which the aperture of the object lens was about 1 inch; the distance of the object from the object-glass 7 inches, and the length of the whole instrument a little less than three feet. The magnifying power was from 60 to 70, and therefore the focal length of the eye-glass must have been about $\frac{1}{2}$ an inch, so as to magnify by itself 12 or 13 times. This instrument is said to have given great satisfaction. The same idea had occurred long before to our countryman Benjamin Martin, who, in his description and use of a polydynamic microscope, has shewn that the achromatic perspective may be easily applied for this purpose.

Various improvements were made upon the microscope by Mr. Cuff, Mr. Benjamin Martin, Mr. Adams,

* Delebarre described his microscope in a memoir which was read at the Academy of Sciences in 1777, and in a separate pamphlet, entitled *Description et l'Usage du Microscope Universel.*

and other opticians; but as they relate principally to the method of fitting them up, and of rendering them more commodious and universal in their application, we cannot enter into any detailed account of their respective improvements, which will be better seen in the account of the instruments themselves.

Having thus given a short account of the history of the compound microscope, we shall now describe some of the most interesting forms in which it has been fitted up.

I. *Cuff's Double Constructed Microscope.*

This instrument is represented in Plate CCCLXXVII. Fig. 19, where ABC is the body of the microscope, having an eye-glass at A, an amplifying lens at B, and a magnifier screwed on at C, and shewn separately at Q. The body of the microscope is supported by the arm DE, fixed on the sliding bar F. The principal pillar *a b* is fixed on the box *b e*, and the brass foot *d* is screwed to the mahogany pedestal XY, having a drawer to contain all the apparatus. The bar F is tightened by a milled headed screw O, when the adjusting screw *c g* is used. The objects are laid upon the stage *p q*, with a hole *n* in its centre, and the light thrown upon them by the concave mirror G.

The following are the different parts of the apparatus which accompany the microscope:

- H a convex lens for concentrating the rays of the sun upon the objects.
- L a cylindrical tube open at each side, and having a concave silver speculum screwed to the lower end *h*.
- P the tube for holding the lens K, with an inner tube, which is forced upwards with a spiral spring. The sliders are thrust between the plates *h* and *i*. The lower end of P goes into the hole *n* in the stage. The hollow part at *k* is intended to receive a glass tube N.
- R is a brass cone, which is occasionally put in the bottom of the cylinder P to intercept the light.
- S is a box, with a concave and a flat glass for confining small living insects. It is placed upon the hole *n*.
- T is a flat glass to lay objects upon, and *u* a concave one for fluids.
- O is a pair of pliers and a sharp point; and Z a brush, as formerly described.
- W is a round ivory box, for holding circular pieces of mica, and rings for the sliders.
- V is a small ivory cylinder, which goes upon the pointed end of the steel wire O.
- M a fish-pan for holding small fishes, in order to view the circulation of the blood. The tail is spread across the oblong hole at the small end *k*, and tied firmly by a ribbon fixed to it. The knob *l* is to be put through the slit *m* made in the stage, and the tail may be brought below the end C of the microscope.
- X is a wire, by which the glass tubes are cleaned.

In using this microscope, screw the proper magnifier to the end C, place the tube P in the hole *n*, and slip one of the ivory sliders between the plates *h* and *i*. Make the upper edge of the bar DE coincide with the division, having the same number with the magnifier used, and fix it firmly by the nut O. Light being thrown upon the object by the mirror G, apply the eye to the upper end of the microscope, and obtain distinct vision by means of the adjusting screw *e g*.

When the objects are opaque, remove the tube P, and having placed the object on a flat glass *u* under C, or upon one end of the jointed pliers *o p*, screw the concave silver speculum to the end of the cylinder L, and slide this cylinder on the lower part EC of the tube, so that the upper edge of L may coincide with the same number as the number of the magnifier employed. Reflect the light employed from the mirror G upon the speculum *h*, and it will be again reflected from the speculum upon the side of the opaque object next the eye.

II. *Universal Compound Microscope.*

One of the most complete and commodious compound microscopes is represented in Plate CCCLXXVII. Fig. 20. where AB is the body, the eye-glasses being contained in an inner sliding tube, by which their distance from the glass at B can be increased or diminished, and the magnifying power of the instrument altered. The body AB is attached by a screw to the arm CD, which may be moved through a square socket over the object. The stage NIS moves up and down the square bar EF by means of the rack and pinion M; and this bar, with all its accompanying apparatus, moves round a joint at the top of the great pillar V, supported upon the three feet G, G, H. By the aid of this joint, the microscope may be put into a horizontal, a vertical, or an oblique direction. At the stage NIS is a sliding brass spring N for confining slips of glass, or large sliders, when the microscope is to be used out of the horizontal position. The lens U is intended to concentrate or modify the light reflected from the mirror G, and it may be adjusted to a proper distance by means of two small screws, one of which is seen at *u*. In candle light this lens is of great use, and it may be turned aside on a joint when it is not required. Six magnifying lenses are set in a brass wheel, screwed in a circular box P. The wheel may be moved round its centre by the action of the finger on its milled rim, and it stops by a click the instant that any of the magnifiers comes into its exact position in the axis of the other lenses. The lenses are numbered from one to six, and the proper number appears in a small opening made in the upper side of the box P. This box screws into the arm CD, and may be taken off when required. If we unscrew the body AB, the intsrument becomes a single microscope by looking directly through any of the lenses in the wheel. The mirror O may be moved up or down the bar EF, by pushing against the screw at *r*. In addition to the apparatus already described, as belonging to single microscopes and to Cuff's compound microscope, the following may be enumerated. A moveable stage W, which is applied to the hole S of the stage by the pin *a*, and has thus a horizontal motion under the field of view. A very deep concave lens *r* is fitted to the large hole of this stage, and also the concave and plane glasses *s* and *o*, while to the small holes *x*, *x*, a black and white piece of ivory *w* is fitted for opaque objects, and a concave and plane glass similar to *o* and *s*. The arm CD is sometimes furnished with rack work, to turn the pinion above, so as to move the magnifiers in the most accurate manner over the objects; and the stage NIS is sometimes jointed, in order to turn by a screw and teeth in a horizontal direction. In using this microscope, the slider-holder K, containing a slider of objects, is placed in the stage NIS, and the arm CD is moved in its socket, till a mark on the side is brought to the edge of the socket. The arm is then turned, till the magnifier is directly over the object, the eye being then placed at the upper end of the tube AB, and the light reflected strongly up into it from the mirror O. The pinion M is then turned to the right or left till the object is seen in the most distinct manner. When the objects are opaque, the slider-holder K is removed, and either the concave glass, or the jointed pliers, are placed on the stage. The concave silver speculum *e* is then screwed into the arm *a*, which is placed on the stage, with the cylindrical part passing through the hole 1; and the light being reflected upon the speculum from the mirror O, it will be strongly condensed by it, and thrown upon the opaque object.

If we consider the construction of the different compound microscopes which have been described, it will be obvious, that a great deal must depend on the accuracy with which the axes of the small magnifying lenses coincide with the axis of the instrument, or that of the eye-glasses. The difficulty of effecting such a coincidence is very great, and we believe is in a great measure overlooked. We conceive, therefore, that the tube which holds the magnifying lenses should have an universal motion, so that, by means of screws, the axis of the lenses could be brought into perfect coincidence wih the axis of the eye-glasses.

III. *Amici's Reflecting Microscope.*

We have already seen that the reflecting microscope of Dr. Barker was nothing more than the Gregorian telescope, with its tube lengthened so as to permit it to act as a microscope; and that the reflecting microscope of Dr. Smith was the Cassegrainian telescope fitted up in a similar manner. The new reflecting microscope constructed by Professor Amici of Modena, and with which he has made several important discoveries, is in like manner the Newtonian telescope converted into a microscope.

It consists of a horizontal brass tube ABCD, Plate CCCLXXVII. 12 inches long, and $1\frac{1}{10}$ of an inch in diameter. A concave metallic speculum AB, having its reflecting surface a portion of an ellipsoid, whose foci are F and *f*, is placed at one end of the tube; the distance AF being $2\frac{6}{10}$ inches, and A*f* 12 inches. A small arm *rs* within the tube, carries a plane speculum of an oval form, placed at the distance of $1\frac{5}{10}$ inches from AB, supported by an oblique section of an metallic cylinder, $\frac{5}{10}$ of an inch in diameter, and inclined 45° to the axis F*f* The object is placed below the tube at MN, and as far before the mirror *s* as the focus F of AB is behind it; and it is supported by a moveable object-bearer attached to the pillar below it. The diameter of the tube ABCD is about $1\frac{1}{10}$ inches, and the thickness of its metal $\frac{1}{20}$th. The object is always placed at the distance of half an inch from the edge of the tube, and may therefore be illuminated by a convex lens, attached in the usual way to the stage or object-bearer. A large concave illuminating mirror below for throwing light upon transparent objects, has a diameter of about 3 inches, and a focal length of about $2\frac{5}{10}$. M. Amici has been able to apply to this instrument a power of *one million**, calculating the number of times that the superficies is magnified, whereas the best microscopes of Adams, Dollond, Delebarre, do not magnify more than 225,000, or about 475 times in diameter. See *The Edinburgh Philosophical Journal*, Vol. i. p. 135, where a more detailed account of this instrument will be found.

IV. *Dr. Brewster's Reflecting Microscope.*

This instrument, which will be understood from Plate CCCLXXVII. Fig. 22, possesses several advantages, and in particular that of being applicable to the stand and apparatus of any compound microscope. Though it is drawn in a horizontal position, it is intended to be placed vertically. It consists of a concave speculum AB, whose surface is a portion of an ellipsoid, having F and *f* for its foci. It is perforated at O, like the speculum of a Gregorian telescope; and between this aperture and F is placed a small convex speculum *s*, whose surface is part of an ellipsoid, having F and ϕ for its foci, $s\,\phi$ being equal to MN, the distance of the object. The back of the speculum is ground into a concave form *a b*, for the purpose of condensing the light upon the object MN. The rays diverging from MN are made to diverge still more by reflection from the small mirror *s*, so that F is their virtual focus; and these reflected rays, falling upon the speculum AB, as if they had diverged from one of its foci F, will be reflected to *f*, and there form a magnified image, which will be again magnified by the eye-glass placed at LL. The convex mirror *s* is carried by the arm *s r*, which is moved by means of the screw *r* T, so that F is one of its foci. An object placed at MN will therefore be seen very distinctly by a microscope of this kind; and it has such a distance from the mirror AB, as to be capable of receiving any degree of artificial illumination. If this microscope is placed vertically in the arm ED of the compound microscope shown in Fig. 19, made large enough to receive it, it may be used along with all the apparatus adapted to that or to any other compound microscope. If a change of magnifying power is required, we have only to use a deeper eye-glass LL; and as the place of the object is not altered by this change, the concave illuminating speculum *a b* will still condense upon the object MN, the light reflected from the great mirror G, Fig. 19.

V. *Mr. Waddel's Compound Microscope.*

A very ingenious and useful compound microscope, represented in Plate CCCLXXVII. Fig. 23. Nos. 1, 2, and 3. has been constructed by Alexander Waddel, Esq. Leith, which possesses many advantages. It is founded on the properties of the astronomical telescope; which, as it inverts the objects, has a right-angled triangular prism A affixed to the outer end of it, at a certain point in the anterior focus of the object-glasses; and by placing the instrument in a vertical, but somewhat inclined position, as in No. 1, and the eye at the dioptric eyepiece E, a picture will be seen within it of the external objects, *erect*, but *reversed*. If this instrument be placed in a horizontal position, as in No. 2, and another right-angled triangular prism affixed to the outside of the eyepiece at E, in a position perpendicular to the other prism, and the instrument so placed that external objects come into it from the observer's left hand side, then, by placing the eye at the last mentioned prism, and adjusting the

* This is 1000 times reckoned in the usual way.

sliding tubes to the sight, a picture of the external objects will be seen distinctly formed within the instrument exactly as it is in nature, neither being inverted nor reversed; and if this last prism have an opening in the lower side of its cover, as in the camera lucida, by a similar adjustment of the eye, the picture within the instrument will appear to be painted on a table under the prism, and may be copied by drawing with a pencil the outline, on a paper placed for that purpose, as is done in the camera lucida.

The way in which Mr. Waddel has commonly made use of this instrument as a *compound microscope* is, by placing it on a stand in a vertical but somewhat inclined position, as at first mentioned, with one of its prisms affixed to the object-end of it; and when the whole of the tubes are drawn fully out, the length of the instrument from the extremity of the prism at one end, to the outside of the eye-piece at the other, is from 9 to 10 inches; which length has been found by the aid of two object-glasses of a compound focus, of about one and a half inch, and a Huygenian eye-piece, with a double eye-glass, of a compound focus of about three-fourths of an inch, to produce a magnifying power, in surface, of about 1020 times, and by applying to the outside of the said object prism an additional magnifier, a much greater power is obtained.

The largest tube of this instrument is less than two inches in diameter; and when the other three sliding tubes are pushed into it, with the prism attached to the object end of it, the whole length very little exceeds 5 inches. From its particular construction, it produces, as an astronomical telescope, a magnifying power of about two and a half times, and the field of view subtends an angle of about 30 degrees. It will be seen from this description of the instrument, that it not only combines the properties of a compound microscope, but of a camera obscura, camera lucida, and diagonal mirror; and that in the first and last of the three foregoing positions, it also becomes an excellent drawing instrument by the aid of a micrometer placed within it near the field-bar of the eye-piece.

An instrument of this construction has been found very useful in botanical and mineralogical pursuits, as objects may be viewed by it under different circumstances with the object-prism, by drawing out or pushing in the sliding tubes, which increases or diminishes the magnifying power at pleasure, without the application of any additional magnifier.

As objects viewed by this instrument are reversed when only one prism is employed, and as certain imperfections arise from the increase of refraction and reflection, when two prisms are used, to render the objects neither inverted nor reversed, it occurred to Mr. Waddel, that some advantages might result from uniting the two prisms in one, as in Fig. 23 No. 3; which he effected by forming two right-angled triangular prisms out of one piece of glass, in such a way that the two reflecting surfaces were at right angles to each other. When a prism of this construction is applied to the object end of the instrument, with one half of it placed in the axis, and the other half without, and the instrument held in a vertical position, so as to admit external objects from the observer's left hand, then, by looking into it with the dioptric eye-piece, a picture will be formed as in nature, neither inverted nor reversed, which may be correctly copied by the aid of the micrometer before mentioned; and when at the other end, becomes a camera lucida. Transparent objects may also be viewed by this instrument in the ordinary way, either with or without the prism affixed to the object end of it.

VI. *Description of a New Compound Microscope for examining objects of Natural History* *

" The construction both of single and compound microscopes has, within the last fifty years, been brought to a great degree of perfection; and, for all the purposes of amusement and general observation, these instruments may be considered as sufficiently perfect. But when we employ the microscope as an instrument of discovery, to examine those phenomena of the natural world which are beyond the reach of unassisted vision, and when we use it in ascertaining the anatomical and physiological structure of plants, insects, and animalculæ, we soon find, that a limit, apparently insuperable, is set to the progress of discovery, and that it is only some of the ruder and more palpable functions of these evanescent animals that we are able to bring under observation. Naturalists, indeed, are less acquainted with the organization of the microscopic world, and the beings by which it is peopled, than astronomers are with those remote systems of the universe which appear in the form of nebulæ and double stars. It was the improvement of the telescope alone which enabled Dr. Herschel to fix the views of astronomers upon those regions of space, to which, at a former period, their imaginations could scarcely extend; and when the microscope shall have received a similar improvement, we may look for discoveries equally interesting, though less stupendous, even in those portions of space which are daily trampled under the foot of man.

" It is both important and interesting to inquire into the cause of this limitation of microscopical discovery. The construction of single lenses for the simplest form of the instrument, has been brought to great perfection. I have in my possession glasses executed by Mr. Shuttleworth, of the focal length of $\frac{1}{50}$, $\frac{1}{40}$, and $\frac{1}{30}$ of an inch, which are ground with great accuracy; and the performance of single lenses has been recently improved by Dr. Wollaston, as described in p. 240. We cannot, therefore, expect any essential improvement in the single microscope, unless from the discovery of some transparent substance, which, like the diamond, combines a high refractive power with a low power of dispersion.

" In the combination of single lenses to form the compound microscope, opticians have likewise arrived at a great degree of perfection. The aberration of refrangibility can now be completely removed by a suitable arrangement of the individual lenses; and every artifice has been exhausted in suiting the apparatus to the various tastes of purchasers, and to every purpose of popular observation.

" No attempt, however, appears to have been made by opticians to fit up the microscope as an instrument of discovery, to second the labours of the naturalist in preparing the subjects of his research, and to *accommodate the instrument to that particular kind of preparation which is indispensably necessary for the preservation and inspection of minute objects.*

* From Dr. Brewster's *Treatise on New Phil. Instruments, p.* 401—410.

"In perusing the writings of those naturalists who have applied the microscope to the examination of minute objects, we find, that the most difficult and perplexing part of their labour consisted in preserving and preparing the different insects and substances which they wished to inspect. Small insects instantly shrivel up and lose their natural form as soon as they are killed, and the minute parts of plants suffer a similar change from exposure to the air. Hence Swammerdam and Lyonet killed the insects which they meant to examine, by suffocating them either in water, spirit of turpentine, or diluted spirits of wine. The softness and transparency of their parts were thus preserved during the process of dissection, and when they were completely developed, the insect was allowed to dry before it was presented to the microscope. Its parts were consequently contracted, and lost not only their proper shape, but that plumpness, and that freshness of colour which they possessed when alive.

"In the preparation, indeed, of almost every object of natural history that is composed of minute and delicate parts, it must be preserved by immersion in a fluid; the dissection must often be performed in the same medium; it must be freed from all adhesive and extraneous substances, by maceration and ablution in water; and when it has undergone these operations, it is in a state of perfection for the microscope. Every subsequent change which it undergoes is highly injurious; it shrivels and collapses by being dried; its natural polish and brilliancy are impaired; the minute parts, such as the hairs and down, adhere to one another, and the general form of the object, as well as the disposition of its individual parts, can no longer be distinctly seen.

"It is therefore a matter of considerable importance to be able to examine the object when wet, and before it has suffered any of these changes; and by fitting up the microscope in the following manner, this may be effected without even exposing the object to the air.

"The object-glass of the compound microscope should have the radius of the immersed surface about nine times the focal distance of the lens, and the side next the eye, about three-fifths of the same distance. This lens should be fixed into its tube with a cement which will resist the action of water or spirits of wine; and the tube, or the part of it which holds the lens, should have an universal motion, so that the axis of the lens may coincide to the utmost exactness with the axis of the tubes which contain the other glasses.

"Several small glass vessels must then be provided, having different depths, from one inch to three inches, and having their bottom composed of a piece of flat glass, for the purpose of admitting freely the reflected light which is intended to illuminate the object. The fluid in which the object has been preserved, or prepared, is next put into the vessel; and the object itself, placed upon a glass stage, or if necessary fixed to it, is immersed in the fluid. The glass vessel is now laid upon the arm of the microscope, which usually holds the object, and the lens is brought into contact with the the fluid in the vessel. The rays which diverge from the object emerge directly from the fluid into the object-glass, and therefore suffer a less refraction than if it had been made from air; but the focal length of the lens is very little increased, on account of the great radius of its anterior surface. The object may now be observed with perfect distinctness, unaffected by any agitation of the fluid;—its parts will be seen in their finest state of preservation;—delicate muscular fibres, and the hairs and down upon insects, will be kept separate by the buoyancy of the fluid; and if the object when alive, or in its most perfect state, had a smooth surface, its natural polish will not only be preserved but heightened by contact with the fluid. Aquatic plants and animals will thus be seen with unusual distinctness, and shells and unpolished minerals will have a brilliancy communicated to their surfaces, which they could never have received from the hands of the lapidary. If the specific gravity of the substance under examination should happen to be less than that of the fluid, and if it cannot easily be fixed to the glass stage, it may be kept from rising to the top by a piece of thin parallel glass, or by a small grating of silver wire stretched across the vessel.

"The method of fitting up and using the compound microscope, which has now been described, enables us, in a very simple manner, to render the object-glass perfectly achromatic, without the assistance of any additional lens. The rays which proceed from the object immersed in the fluid, will form an image of it nearly at the same distance behind the lens, as if the object had been placed in air, and the rays transmitted through a plain concave lens of the fluid combined with the object-glass. If we, therefore, employ a fluid whose dispersive power exceeds that of the object-glass, and accommodate the radius of the anterior surface of that lens to the difference of their dispersive powers, the image will be formed perfectly free from any of the primary colours of the spectrum. The fluids most proper for this purpose are,

Oil of cassia.	Oil of sassafras.
Oil of anise seeds.	Oil of sweet fennel seeds.
Oil of cummin.	Oil of spearmint.
Oil of cloves.	Oil of pimento.

"These oils are arranged in the order of their dispersive powers; and when those at the top of the list are used, the anterior surface of the object-glass will require a greater radius of curvature than when those at the bottom of the list are employed. Thus, in order to render the object-glass achromatic, when it is made of crown glass, and when the fluid is oil of cassia, the radius of the anterior or immersed surface, should be to that of the surface next the eye as 2.5 to 1. Lest these proportions should not exactly correct the chromatic aberration, it would be preferable to make the radii as 2.2 to 1, and then reduce the dispersive power of the oil of cassia by oil of olives, or any other less dispersive oil, till the correction of colour is complete. If the oil of sweet fennel seeds is used, the radius of the anterior should be to that of the posterior surface, as 0.8 to 1."

VII. *On the Magnifying Power of Compound Microscopes.*

When the microscope consists of two lenses, or of one speculum and one lens, the object is magnified from two causes; *first*, from the enlargement of the image produced by the object-lens or speculum, which is always equal to the quotient, arising from dividing the distance of the image from the object-lens or speculum, by the distance of the object from the same; and, *secondly*, from the effect produced by the eye-glass, which is always equal to the quotient arising from dividing the distance at which the eye sees distinctly by the focal length of the eye-glass. The product of these two quotients will therefore be the magnifying power of the microscope. Hence, calling f the focal length of the eye-glass, D the distance of the object from the object-glass, d the distance of the image, and Δ the distance at which the eye sees objects distinctly, we shall have the magnifying power or M, by the following formula,

$$M = \frac{d}{D} \times \frac{\Delta}{f}$$

If a third, or amplifying glass is added, as in the common compound microscope, for the purpose of enlarging the field, the magnifying power of the instrument is diminished, and may be found by multiplying its magnifying power without the amplifying glass, as given by the above formula, by the fraction $\frac{L}{\phi}$; ϕ being the focal length of the amplifying lens and $L = \frac{\delta^2}{\delta - \phi} - \overline{d' - f}$, δ being the distance of the first and second glasses, and d' the distance of the first and third glasses. Hence we obtain the following general rule. Divide the difference between the distance of the two first lenses, or those next the object, and the focal distance of the second or amplifying glass, by the focal distance of the second glass, and the quotient will be a *first number*. Square the distance between the two first lenses, and divide it by the difference between that distance and the focal distance of the second glass. From this quotient subtract the excess of the distance between the first and third glass above the focal length of the third glass, and divide the remainder by the focal distance of the third glass, or that next the eye, and a *second number* will be obtained. Multiply together the first and second numbers, and the magnifying power of the object-glass as found from the rule in p. 243. col. 1, and the product will be the magnifying power of the compound microscope.

The preceding rules for calculating the magnifying powers of microscopes, are founded on the principles which have been adopted by all optical authors; but it will appear, we trust, from a very slight consideration of the subject, that the magnifying power thus found is not the real measure of the assistance afforded by the microscope. Let us take the case of a compound microscope, with two lenses, and let us suppose that the distance of the object from the object-lens is one foot, the distance of the image behind it 20 feet, the focal length of the eye-glass 1 inch, and the distance at which the eye sees microscopic objects 6 inches. Hence the magnifying power of this microscope, computed on the old principle, is $\frac{20}{1} \times \frac{6}{1} = 120$ times; that is, *the object appears* 120 *times larger than if it had been placed at the distance of* 6 *inches from the eye.* But the object is actually placed at the distance of 21 feet from the eye, and the image is not only magnified 20 times by the object-glass, but it is brought to such a distance that the eye can see this magnified image at the distance of 6 inches. Hence the real magnifying effect, by the object-glass alone, is $\frac{20 \text{ feet}}{1} \times \frac{21 \text{ feet}}{\frac{1}{2}} = 840$; and when we look at this image with an inch eye-glass, it is again magnified 6 times, and the total magnifying power is $840 \times 6 = 5040$ times, in place of 120, according to the old principle.

Although this is obviously a correct measure of the benefit which the eye derives from the microscope, and of the effect of the instrument, yet it will be said that, though the object is placed at the distance of 21 feet from the eye, the eye *can* advance to it and examine it at the distance of 6 inches, so that 120 times is the measure of the assistance which the eye receives when it has placed itself in the best position for examining the object. This is undeniable; but we might as well say that a telescope directed to a table of logarithms, at the distance of 1000 feet, did not magnify 20 times (provided that was its magnifying power) because the observer could advance to the book, and see the figures under a larger angle with his naked eye.

If we suppose that the microscopic object is placed in a cavity, whose depth is 12 inches, then, if the observer does advance to it, he cannot see it at a less distance than 12 inches; so that even on the old principle the magnifying power is 240 times. If the object is placed in a position where the eye cannot advance to it at all, then, on every principle, the real power is 5040.

VIII. *On the Method of viewing and illuminating Microscopic Objects.*

The art of illuminating microscopic objects is not of less importance than that of preparing them for observation. No general rules can be given for adjusting the intensity of the illumination to the nature and character of the object which is to be examined; and it is only by a little practice that this art can be acquired. In general, however, it will be found that very transparent objects require a less degree of light than those which are less so; and that objects which reflect white light, or which throw it off from a number of lucid points, require a less degree of illumination than those whose surfaces have a feeble reflective force.

Most opticians have remarked, that microscopic objects are commonly seen better in candle light than in day light, a fact which is particularly apparent, when very high magnifying powers are employed; and we have often found, that very minute objects, which could scarcely be seen at all in day light, appeared with tolerable distinctness in candle light. So far as we know, the cause of this has not been investigated; and as it leads to general views respecting the illumination of microscopic objects, we shall consider it with some attention.

Let LL, Plate CCCLXXVII. Fig. 24, be a single microscope, placed before the eye at E, and let f be a microscopic object, placed in its anterior focus, and illuminated by two candles at A and B. As the rays Afa, and Bfb cross at f, the focus of parallel rays, and as the two shadows of the microscopic object will be formed at a and b, as it were by rays diverging from f, the images of these two shadows formed upon the retina will coincide, and make only one image, so that the object f will appear perfectly distinct. If the object, however, is placed either within or without the focus f, its shadows being formed as it were by rays diverging from a point either within or without, the principal focus f, will not coincide on the retina, but appear to form two images, either overlapping each other, or completely separated. If instead of two candles A, B, we have 4, 5, or 6, we shall have 4, 5, or 6 overlapping or separated images. Now, as it is impossible to place the different parts of a microscopic object exactly in the focus *f*, and as every lens has different foci for the differently coloured rays, and even for homogeneous light, in consequence of its spherical aberration, it necessarily follows, that when microscopic objects are illuminated by light proceeding from several points, the image of it upon the retina must consist of a number of images not accurately coincident; and hence it becomes of the greatest importance that it be illuminated only from one point, and not from a large surface of light, such as the sky, which is equivalent to an infinite number of radiating points.*

The following rules may therefore be laid down respecting the illumination of microscopic objects, and the method of viewing them.

1. The eye should be protected from all extraneous light, and should not receive any of the light which proceeds from the illuminating centre, excepting that portion of it which is transmitted through, or reflected from the object.

2. Delicate microscopical observations should not be made when the fluid which lubricates the cornea of the observer's eye happens to be in a viscid state, which is frequently the case. See Brande's *Journal*, vol. ii. p. 127.

3. The figure of the cornea will be least injured by the lubricating fluid, either by collecting over any part of the cornea, or moving over it, when the observer is lying on his back, or standing vertically. When he is looking downwards, as into the compound vertical microscope, the fluid has a tendency to flow towards the pupil, and injure the distinctness of the vision.

4. If the microscopic object is longitudinal, like a fine hair, or consists of longitudinal stripes, the direction of the lines or stripes should be towards the observer's body, in order that their form may be least injured by the descent of the lubricating fluid over the cornea.

5 The field of view should be contracted so as to exclude every part of the object excepting that which is under immediate examination.

6. The light which is employed for the purpose of illuminating the object should have as small a diameter as possible. In the day time it should be a single hole in the window-shutter of a darkened room, and at night it should be an aperture placed before an Argand lamp.

7. In all cases, and particularly when very high powers are requisite, the natural diameter of the light employed should be diminished, and its intensity increased by optical contrivances.

8. When a strong light can be obtained, and indeed in almost every case, homogeneous light should be thrown upon the object. This may be done, either by decomposing the light with a prism, or by transmitting it through a coloured glass, which has the property of admitting only homogeneous rays.

CHAP. III.

On Solar Microscopes.

The solar microscope is an instrument for representing, upon the wall of a dark room, magnified representations of minute objects, illuminated by the condensed light of the sun. It was invented, in the year 1738, by Dr. Lieberkhun, who, in the winter of 1739, when he was in London, showed one constructed by himself, to several members of the Royal Society, and several opticians, particularly Mr. Cuff and Mr. Adams. Lieberkhun's solar microscope had no mirror for reflecting the sun's rays into the tube; but Mr. Cuff soon saw its imperfections, and constructed one in a very improved form.

Mr. Cuff's solar microscope was composed of a tube, a looking-glass, a convex lens, and a Wilson's microscope. The sun's rays were directed by the looking-glass through the tube upon the object, placed a little before the anterior focus of the convex glass. The image of the object was thrown upon a screen of white paper, and its magnitude was proportional to the distance of the screen from the convex lens.† M Lieberkhun afterwards adapted the solar microscope to the representation of opaque objects; but he did not leave behind him any account of the method which he followed.

M. Æpinus was the first person who described an apparatus for illuminating opaque objects in the solar microscope. If we suppose *e f*, Plate CCCLXXVII. Fig 25. to be the object placed before the convex lens K, he attached to the tube MNOP, two parallel brass plates AB, AC, one of which, AB, moved round a joint at A, and could be placed at any angle with AC by means of the screw C*n* and spring *s*. On the lower end of AB and below K, he fixed a mirror *b d*, which received the rays *a c* from the illuminating glass NP, and threw them upon the front of the object *e f*. By turning the screw C *n*, these rays could be reflected at pleasure upon any part of the object. See *Nov. Comm. Petrop.* vol. ix. p 326.

The solar microscope received great improvements from Mr Benjamin Martin, who has given an account of them, in his *Description and use of an Opaque Solar Microscope*. 8vo. 1774 This instrument is represented in Plate CCCLXXVII Fig. 26—33. with all the parts which are used both for transparent and opaque objects. In Fig. 26. it is shewn as fitted up for opaque objects. In Fig. 27. is represented that part of it, called the single tooth and pinion microscope, which is used for shewing transparent objects. The cylindrical tube Y slides in the tube EF, Fig 26. and in order to use it as a single microscope, a handle *c* screws into a female screw at *g*, and the tube Y is removed. The slider shewn in Fig. 28. and containing six magnifiers, fits

* These observations suggest a new method of finding the principal focal length of a lens LL. Having placed two candles A, B, at a great distance from one another, move a small object backwards and forwards, till it appears to be single. The point *f*, where the two shadows thus coincide, will be the focal point required. The diagram suggests also the construction of a very simple microscopic micrometer, the distance of the body to be measured from *f* affording a measure of its diameter. The length of the scale will increase, as AB, the distance of the lights or luminous aperture, diminishes.

† See *Phil. Trans.* 1749, vol. xli. p. 503. It appears that the apparatus for viewing the circulation of the blood in frogs and mice, was invented by a Dr. Alexander Stuart.

into a dovetail circle P, Fig. 27. The slider at Fig. 29. slides in at *h*, Fig. 27. and is used to condense the sun's rays strongly on the object. Three of them marked 1, 2, 3, are used, corresponding to the numbers in Fig. 28.

The body of the solar microscope is shown at ABCDEF, the part ABCD being conical, and the part CDEF cylindrical. This last part receives the tube G of the opaque object-box. A large concave lens is placed at AB for receiving the rays from the mirror ONP, and converging them into the box HILX.

A brass frame NOP is fixed to the moveable circular plate *a b c*, and carries a plane mirror for reflecting the sun's light upon the convex glass at AB; and by means of rackwork moved by the nuts Q and R, this mirror can be turned into such a position with respect to the incident ray, that the reflected ray passes along the axis of the tubes. The microscope is fastened to a window-shutter by two screws *d*, *e*. The box HILX for opaque objects is shown open. It contains a plane mirror M for reflecting the light from the lens AB upon the object, and this mirror is adjusted through the door *k i* to the proper angle by a screw S. Two tubes of brass are shown at V and K, one sliding within the other, and the outer one V sliding into the box. These tubes carry two magnifying lenses. The interior tube is sometimes taken out, and the exterior one (which is seen within the box) is then used alone.

A brass plate H has its back part fixed to a tube *h* by means of a spiral wire within the tube, which always presses the plate against the side H of the box. The sliders, with the opaque objects shown in Plate CCCLXXVII. Fig. 30. pass between this plate and the side of the box, which is done by drawing out the plate H by means of the nut *g*. The following are the other parts of the opaque solar microscope.

Fig. 32. is a brass quadrangular slider case, to hold any animal or opaque object, which is to be placed at H, like the other sliders.

Fig. 33. is a four glass slider in a brass frame, for animalculæ &c. which is to be placed between the plates at *m*, Fig 27.

Before using the solar microscope, a circle a little larger than *a b c*, must be made in the shutter of a window opposite to the sun. The mirror NOP is then put through this hole, and the square plate applied to the shutter. The places corresponding to the two holes of the screws *d*. *e*, are then marked on the shutter with a pencil, and holes made large enough to admit the screws, which, passing through the shutter, are screwed into their respective holes in the square plate, so as to hold the microscope firmly in its position.

In order to use the microscope for opaque objects, the mirror NOP is turned by the screws Q, R, one of which gives it a circular motion, and the other raises or depresses it, till it reflects the sun's rays through the tube ABEF upon a white paper screen or cloth, from 4 to 8 feet square, placed at a distance of from 5 to 8 feet from the window The tube G of the box HILX is then put into the tube EF, and the mirror M is adjusted through the door *k i* till the objects are strongly illuminated. The door *k i* being shut, a distinct image of the object will be obtained upon the screen, by adjusting the tubes V and K with the magnifiers, which is done by moving them backwards and forwards As the sun is always in motion, it is necessary to shift the place of the mirror NOP, so as to keep the reflected light coincident with the axis of the tube. This effect may be produced in a superior manner by adapting the solar microscope to a Heliostate (see that article) or piece of clock-work, which drives the mirror continually, so as to make it always reflect the sun's light in one direction.

In order to use the microscope for transparent objects, take away the opaque box HILX, and insert the tube Y of Fig. 27. in EF. Place the slider, Fig. 28. in its place at *n*, a condenser, Fig. 29. into the opening at *h*, and the slider, Fig. 32. with the objects between the plates at *m*: then, having adjusted the mirror NOP as before, a magnificent picture of the object will be seen on the white screen.

The solar microscope now described, though possessing all the advantages that can arise from mechanical construction, is still a very imperfect instrument, being liable to all the bad effects arising from the different refrangibility of light.

The only method of remedying this defect, is to correct the colour, either by using a combination of lenses for the purpose of forming the image, or to use a lens composed of differently dispersing and refracting media.

We have already shown in the article Achromatic Telescope, that achromatic eye-pieces may be constructed with two, three, or four lenses, and therefore we have only to substitute one of these eye-pieces in place of the lenses of V and K, Fig. 27. Dr. Robison tried the eye-piece of Ramsden, described in the above article, (where, by the way, one of the focal lengths is stated at 7.025 in place of 1.025) as the magnifier of a solar microscope, and found it to surpass every thing that he had seen. "The picture formed by a solar microscope," says he, "is generally so indistinct, that it is fit only for amusing ladies, but with this magnifier it seemed perfectly sharp. We therefore recommend this to the artists as a valuable article of their trade."

Another mode of improving the solar microscope has been described by Dr. Brewster, in his *Treatise on New Philosophical Instruments*, and is founded on the principle already explained, (see p. 248.) as applicable to the compound microscopes.

The method of fitting up the solar microscope, to render it susceptible of this improvement, is represented in Plate CCCLXXVII. Fig. 34. where AB is the illuminating lens which receives the parallel rays of the sun, and throws them upon the object. The object lens CD is firmly cemented into one end of a tube *m* CD *n*, which has a tubular opening at E; and at the other end of the tube is cemented a circular piece of parallel glass *m n*. The tube *m* CD *n* is then filled with water, or any other fluid; and the object, when fixed upon a slider, or held with a pair of forceps, is introduced into the fluid at the opening E. The slider, or the forceps, may be easily rendered moveable, so that the object may be placed at a proper distance from B; or the adjustment may be effected by a motion of the screen on which the image is projected. The plate of glass *m n* might be removed, and the whole of the space between AB and CD filled with fluid; but if the fluid had any tinge of colour, the transmitted light would, in this case, partake of it, and injure the distinctness of the image.

If the microscope is fitted up for the examination of transparent bodies, it is obvious, that the image will be much more perfect than if it had been formed in the common way. The opacity which arises from a contraction of parts is thus completely removed, and an additional transparency is communicated by the fluid, which could not have been obtained in any other way. Substances, indeed, which with the common solar microscope appear opaque, will, in the present form of the instrument, exhibit a very great degree of transparency. The advantages arising from immersion in a fluid, which have been very fully stated in Chapter II. p. 248, apply with peculiar force when the objects are used in the solar microscope.

This microscope may be rendered perfectly achromatic, by using the same fluids, and by giving the lens nearly the same radii of curvature, which have been already mentioned.

CHAP. IV.

On the Lucernal Microscope.

The lucernal microscope is an instrument for exhibiting to one or more persons magnified representations of microscopic objects when illuminated by an Argand lamp. It was invented by Mr. Adams, and has the property of enabling the observer, who has no knowledge of drawing, to make an exact delineation of the object he is examining.

It is represented in Plate CCCLXXVII. Fig. 35, 36, 37, and 38. In Fig. 35. it is fitted up for viewing opaque objects, and consists of a large pyramidal box of mahogany ABCDE, about 14 inches long, and six inches square at its large end. This box is supported on a brass pillar FG, by means of the socket H, and the curved piece IK. At N is a dove-tailed piece of brass for receiving the dove-tail at the end of the piece LMN. The part MN consists of two brass tubes, one sliding within the other, and the inner one carries the flat piece of brass LM, at the top of which is a hole L for the eye. This piece may be raised or depressed, and fixed in any position by a milled screw at M, and it may be made to approach to or recede from the box, by pulling out or pushing in the tube M to which it is attached. At the other end of the box is fixed a tube P, which receives another tube O, at the end of which the magnifiers are fixed. A long square bar RS, which passes through the sockets YZ, carries the stage *f g h i* that holds the objects. This bar may be moved backwards or forwards, for the purpose of adjusting the stage, by means of a pinion at *a* working in a rack; and this pinion is moved either by a handle *b c* furnished with an universal joint, or by the screw-nut shown separately in Fig. 36. The body of the microscope is kept steady by the brass bar *d e*, which sustains the curved piece KI.

The objects are placed in the front side of the stage *f g h i*, between four small brass plates, the edges of two of which are seen at *k* and *l*. The two upper pieces of brass, which are moveable, are fixed to a plate which is acted on by a spiral spring, that presses them down and confines the slider. This plate, and the two upper pieces of brass, are lifted up by the small nut *m*.

The Argand lamp, shown in Fig. 37. throws its light upon a glass hemisphere *n*, which conveys it to the concave mirror *o*, from which it is reflected upon the objects.

When the stage for transparent objects, shown in Fig. 38. is to be used, the upper part *f g r s*, of the opaque stage is taken out, and the two legs 5 and 6 of the transparent stage fit into the under part *r s*. The sliders are confined at 7, and the lenses for condensing the light are placed in the brass tubes 9, 10, which may be drawn out or pushed in by the pin 11. The magnifiers are screwed into the hole 12, and are adjusted by the nut 13, working in a rack 1, 2.

At the end AB of the wooden body, there is a slider represented as partly drawn out at A. When it is taken completely out, three grooves will be seen, one of which contains a board forming the end of the box, the next a frame with a ground glass, and the third, (or that farthest from AB,) two large convex lenses.

When the instrument is fitted up as shown in the figure, it is ready for adjustment. The lamp being placed before the glass hemisphere *n*, the mirror *o* must be inclined till it receives the light from the hemisphere, and reflects it upon the objects. The wooden slide A being taken out, and the cover and the ground glass removed from their respective grooves, the piece LM is pulled out or pushed in, and raised or depressed till the eye at L sees the large lens placed at the end AB of the wooden body, filled by an uniform field of light. The eye still looking through the aperture at L, the lenses are adjusted to their focal distance by turning the pinion A, and the ground glass is placed before the large lenses. The image of the objects will now be seen beautifully depicted upon the ground glass, and may be accurately delineated upon it with the point of a pencil. The objects, when magnified, are seen to the greatest advantage by a single observer, when his eye is applied to the aperture L, but if two or three persons wish to see the objects at the same time, the guide LM must be removed. The large lens must be taken out of the groove, and the image received on the rough glass.

Some slight improvements have been made on the Lucernal microscope by opticians, and by the Rev. Dr. Prince and Mr. Hill, an account of which will be found in Adam's *Essays on the Microscope*, 2d Ed. p. 84, &c.

Account of a New Method of illuminating Objects in the Solar and the Lucernal Microscopes.

The great effects which still attach to the solar and lucernal microscopes, arise from the imperfect method of illuminatiag the objects. The method suggested by Æpinus, and employed almost universally by opticians, of reflecting the light concentrated hy a lens upon the objects by means of a plane-mirror, is good enough so far as it goes; but in consequence of the light arriving from one direction only, the surface of the illuminated object is covered with deep shadows; and the intensity of illumination is by no means sufficient when the power of the instrument is considerable.

We propose, therefore, that in the solar microscope the sun's light should be reflected by a very large mirror through four apertures, A, B, C, D, each of which is furnished with an illuminating lens, such as NP, Fig. 25. or *n*, Fig. 35. The four cones, if condensed, are then received before they reach their focus, by an inclined mirror, such as *ab*, Fig. 25. or *o*, Fig. 35. which reflects them upon the object *ef*; the distance $ab+bf$ being always less than the focal length of the illuminating lens NP. In the lucernal microscope, it would be adviseable to place an Argand lamp opposite each of the apertures A, B, C, D. By these means the light would fall upon the surface of the object in four different directions; a high degree of illumination would be obtained for very dark objects, or for high powers; and by shutting up one or more of the four lenses, or parts of them, we should be enabled to find the particular direction of the light which is best suited for developing the structure, which it is the object of the observer to discover.

CHAP. V.

On Microscopic Objects.

Almost every object in nature may be considered as an object fit for the microscope, either as a whole, if it is small, or in its parts, if it has considerable magnitude. The name of microscopic objects, however, is generally given to those minute animals which cannot be seen without the microscope, or to particular structures in the animal, vegetable, and mineral kingdom, which are remarkable for their beauty when examined by the microscope.

In our article ANIMALCULE, we have already entered into great detail respecting the most interesting animals which have been discovered by the microscope, and have represented some of the most important in Plates XXIII. and XXIV. We shall therefore confine ourselves at present to a brief enumeration of microscopic objects which possess a particular interest.

List of the most interesting Microscopic Objects.

I. *Animalcules.*

Hydræ, or polypi, found in stagnant water.
Animalcules found in infusions of hemp seed.
Do. in milk, blood, urine, and other animal fluids.
Do. in fetid sea-water.
Do. in infusions of grass and hay.
Do. in dunghill water.
Do. in infusions of pepper, coriander seeds, and cassia, and in the juice of the beet root, &c.
Do. in an infusion of the *sonchus arvensis.*
Do. in water where duckweed grows.
Do. in yellow ochry slime that covers pools of standing water.
Eels found in paste.
Do. in vinegar.
Do. in salt water.
Do. in blighted wheat.

The animalcules are generally found in the film or pellicle which covers the surface of infused liquors. It is sometimes necessary to dilute the infusions, which should always be done with distilled water, and the water should be previously examined in the microscope. The animalcules are commonly seen best when the water is a little evaporated.

II. *Insects.*

The common spider, the flea, the bug, mites of a cheese, the gnat, the common louse, the crab-louse, the pigeon-louse, the cattle-louse, the sheep-louse or tick. The death-watch of Linnæus. The podura viridis and aquatica, found on the leaves of plants. The rose-chaffer, the flee beetle. the water-flee, the lady-cow or lady-bird, various species of the genera *Coccinella, Chrysomela, Curculio, Gryllus, Cicada, Cimex, Aphis,* and *Chermes.* The water-scorpion, the mole-cricket, the glow-worm, the earwig.

The LEPIDOPTEROUS insects of the genera *Papilio, Sphinx,* and *Phalæna,* are interesting, from their wings, scales, feathers, proboscis, head, eyes, antennæ, chrysalides, eggs, legs, &c.

The NEUROPTEROUS insects of the genera *Libellula, Ephemera, Phryganea,* &c. from their head, wings, eyes, and antennæ.

III. *Parts of Animals.*

Wings, and legs, and eyes, of flies and other animals.
Scales of fishes. Antennæ of moths and butterflies.
The hair and bristles of animals.
Globules and circulation of the blood.
Feathers } Pith of the feathers cut transversely.
Skins }

IV. *Parts of Plants.*

Section of the trunk and roots. The rhind.
The seeds of plants. The blea.
The stamina.
The pistil. The leaves and their fibres.
The receptacle. The pericarpium.

V. *Sections of Plants.*

The following is a list of the vegetable sections which were made by Mr. Custance, by means of a machine which has been described in the *Phil. Mag.* vol. iii. p. 302. by Dr. Thornton.

English oak. Evergreen, do.
Norway oak. Ash.
Cedar. Cork.
Savin. Fir.
Ceanothus. Hazel.
Lime. Elm.
Elm root. Mulberry, do.
Grape-root. Lime, do.
Beech. Birch.
Plum. Ivy.
Spanish elder. American climber.
Cissampelos. Virgin's bower.
Magnolia grandiflora. Golden rose.
Althæa frutex. Tulip tree.
Spanish chesnut.
Platanus orientalis. Viburnum lantana.
Oak-root. Ash-root.
Asp-root. Walnut, do.
Grape vine. Indian turpeth.
China root. Jasmine.
Dog-rose. Raspberry.
Barberry. Briar.
Elder-root. Ditto, branch.
Willow-root. Ditto, branch.
Mulberry.
Sycamore. Maple.
American dogwood. Ptelea trifoliata.
Ligneous night-shade. Sumach.
Apricot. Medlar.
Bay. Laurel.
Sea-weed. Longitudinal cutting of plane tree.
Ditto of Spanish elder. Ditto of briar.

Common cane. Ditto with curious centre.
Bamboo cane. Sarsaparilla.
Longitudinal cuttings of sugar-cane. Elder.
Rose-tree.
Longitudinal slices of elder.
Ditto grape vine. Transverse, ditto.
Dogwood. Plane tree.
Beech. Grape vine.
Spanish chesnut. Walnut.
Fig. Ditto Longitudinal.
Asparagus. Artichoke.
Thistle. Fennel.
Parsley. Ditto root.
Sun-flower. Ditto root.
Agrimony. Eryngo.
Potato-stalk. Centaurea
Indian reed. Indian corn.
Amaranthus. Bromelia pinguin.
Campanula. Monk's hood.
Lavatera. Solidago.
Mugwort. Chrysanthemum.
Helianthus. Wormwood.
Bulrush. Portugal reed.
Burdoch.
Field-mustard. Aloe-flower stalk.
Solomon's seal. Tulip.
Calamus aromaticus. Buckbean.
Gourd. Melon.
Crown imperial. Flower de luce.
Pine apple. White lily.
Asparagus. Ragwort.
Water-flag. Sugar cane.
Stems of leaves of hog's fennel. Hemlock.
Chesnut. Wild turnip.
Stems of the leaves of Red dock. Horse-radish.
Cabbage. Carrots.
Roots of phytolacca. Teasel.
Carrot. Fennel.
Stinging-nettle roots curiously variegated.
Roots of parsley and wormwood variegated.
Stalks of fern with variations.
Charcoal.—See *Phil. Mag.* vol. iii. Plate VIII. Fig. 5.

VI. *Worms, &c.*

The Gordius aquaticus and lacustris. The common leach, the horse-leach, and the sea-leach. The ascaris vermicularis and lumbricoides. The earth-worm, the sea-worm, the gravel worm. Black, red, and grey snails. The sea lemon. The sea mouse. The nereis noctiluca. The sea-nettle and sea limp. The asterias. Corals, madrepores, millepores, cellepores. Zoophytes, such as sponges, &c.

VII. *Saline Solutions.*

All the alkaline, earthy, and metallic salts, form very interesting microscopic objects when dissolved in water, and allowed to crystallize on a plate of glass by evaporation.

In order to see in perfection, however, the mode in which these bodies crystallize, it is necessary to illuminate them with polarized light, which is best done by substituting in place of the mirror four or five plates of glass laid above each other, so as to reflect the light up the tube at an angle of about 56°, and to apply to the eye-glass a thin plate of agate or tourmaline for the purpose of analysing the transmitted light. The crystallizations will then appear of the most beautiful colours, the tints always varying with the thickness of the crystals.

Description of Microscopic Objects represented in Plate CCCLXXX. and copied from those given by Mr. Adams.

Fig. 1. Is the lobster insect, which is found on the legs of a fly, and also occurs in books and paper, and in plants.
Fig. 2. Is an insect denominated the *Thrips Physapus*, which is found on the Dandelion and other plants and flowers. The body is black, and the wings white.
Fig. 3. Represents the *Cimex Striatus*, a beautiful insect, with its colours very bright, and elegantly arranged. It is found in June on the elm tree.
Fig. 4. Represents the *Chrysomela Asparagi*, which is found in June on the asparagus, after it has run to seed.
Fig. 5. Is the *Meloe Monoceros*, found on umbelliferous plants.
Fig. 6. Represents a scale from the sole fish.
Fig. 7. Is a section of a weed called the fat hen, which grows among rubbish.
Fig. 8. Is the section of a reed from Portugal.
Fig. 9. Is a section of the bamboo.
Fig. 10 Is a section of the hazel.

MIDDLEBURG. See WALCHEREN.

MIDDLEMOST KEYS in *music*. The key-notes, thus denominated by Dr. Robert Smith, (p. 164, 2d edit. of his *Harmonics*,) are D and A; which keys have, on the common or 12-note instruments, only one false consonance in each, both of them discords, viz. the 5th of D, (for want of A♭), and the 4th of A (for want of D♯): if one key be added on each side, downwards and upwards, in the order of modulation (by Vths,) these four middlemost keys, viz. G, D, A, and E, (which are the open strings of the violin,) have all their concords true, or according to the system of temperament adopted in the tuning of the instrument; but in G, the 2nd and the 5th are false, and in E, the IVth and the VIIth are false, for want of notes for A♭, D♭, A♯, and D♯. In modulating, either upwards through the keys B F♯, C♯, &c. or downwards through the keys C, F, B♭, &c. the number of false consonances are in either case 3, 4, 5, &c. respectively, increasing in arithmetical progression. It appears from the investigations of Professor Fisher, which have been referred to in our article MEAN TONE SYSTEM, that the frequency of the use of the middlemost keys, D and A, in organ music, is in each case more than double of the use of the key of C, as to frequency.

MIDDLESEX, an inland county in the south-east of England, is bounded on the south by Surry, and a small part of Kent; on the north by Hertfordshire; on the east by Essex; and on the west by Buckinghamshire. Its boundaries on all sides, except the north, are natural; the Thames dividing it from Surry, the Lea from Essex; and the Coln from Buckinghamshire. Its form approaches somewhat to that of a quadrangular; but on its southern side, it is rendered very irregular by the windings of the Thames; and on the northern, a portion of it projects into Hertfordshire. It is inferior in size to all the English counties except Rutlandshire and Huntingdonshire; the medium length is about 20 miles, and the medium breadth 14 miles: its greatest length, from east to west, is 22 miles; and its greatest breadth, 17 miles. Its area is variously computed: Mr. Middleton says it contains 280 square miles, or 179,200 acres. According to the returns to Parliament of the poor rates, drawn up under the inspection of Mr. Rose, it contains 190,080 acres; while other statements extend its area to 217,600 acres. It is divided into 6 Hundreds, viz. Edmonton, Ossalston, Elthorne, Gore, Isleworth, Spelthorne; and into 2 Liberties, viz. Finsbury and Wenloxbarn: the hundred of Ossalston is subdivided into 5 parts; in this hundred London is situated. Besides the metropolis of the British empire, and its contiguous villages, the county of Middlesex contains, as towns of size or consequence, Brentford, Uxbridge, Enfield, Hounslow, &c. being places of very inferior size and population. Besides the parishes which constitute London in its most extended sense, there are in Middlesex 62. This county returns 8 members to parliament; viz. 4 for the city of London, 2 for the city of Westminster, and 2 for the county. It is in the province of Canterbury, and in the diocese of London and Westminster.

Near the banks of the Thames, Middlesex is extremely flat; but as we approach its northern confines, its surface becomes more varied, though in no part can it be called high. The principal hills are at Highwood, Howden, Barnet, Harrow, Highgate, and Hampstead; the last, which is said to be the highest ground in the county, is not more than 400 feet above the Thames. The most picturesque part of the county lies to the north-west of Hamstead, and in the vicinity of Howden; the surface here is undulating, and as there is a sufficiency of wood, and the fields are rich and verdant, the appearance is beautiful as well as picturesque. The soil of Middlesex is not naturally very fertile; the low parts of the county are either of a gravelly or sandy nature; and their fertility is almost entirely owing to manure; gravel and sand are likewise found on some of the highest hills. The best soil lies on the sides of the larger hills, and on the banks of the rivers; these soils are either a strong loam, or a deep, rich, friable loam. In some parts, as near Pinner and Edgware, the soil is a loamy clay. The subsoil, through the whole county, is a gravel strongly tinged with oxid of iron. Indeed the only difference over the whole of lower Middlesex, arises from the greater or less depth of this gravel. Wherever the soil is strong, the gravel lies at a considerable depth; and this is also the case on the alluvial lands, near the Thames and other rivers; but wherever the upper soil is light, there the gravel is comparatively near the surface. All the hollows, bowls, and chinks, are filled with gravel; and the summits of most of the highest hills consist of sand and gravel. This subsoil is also found below the heathy land, between Rickmansworth and Staines. The Isle of Dogs, the flat land on the borders of the Lea and the Coln, and some of the land on the Brent, is marsh soil. The climate of Middlesex is mild, especially on its southern side, near the Thames. Even at the short distance, however, of Highgate and Hampstead, partly owing to the greater elevation, and partly to the soil being stronger and more retentive, the air is considerably sharper. The prevalent winds are from the west and south west, and from the east and north-east; the last prevail in the spring months often for several weeks, and accompanied with a considerable degree of cold. The quantity of rain that falls is less than in most other counties of England, the average not exceeding 24 inches. July is generally a wet month; perhaps the wettest in the year; if not wet, it is often the hottest. The cold in winter is seldom very great; nor does much snow fall, or continue long on the ground. The principal rivers are the Thames, the Lea, the Coln, and the Brent. The Thames first touches the borders of the county near Staines, where it is joined by one of the branches of the Coln; near Brentford, where it inclines to the north, it is joined by the Brent, and, as it leaves the county, it is joined by the Lea. This last river is navigable from the Thames to near Tottenham, about eight miles, where a canal is cut which runs parallel to the river, forming a water-course along the whole eastern border of Middlesex. The New River, as it is called, rises in Hertfordshire, 19 miles from London, though, by its serpentine course, its length is nearly 36 miles. It has 43 sluices, and over it are 215 bridges. Middlesex is intersected by two canals for the purposes of navigation, the Grand Junction and Paddington; the former joins the Thames at Brentford, running by Hanwell, Uxbridge, Harefield, &c.; it admits barges of 70 tons; the rise of water, from its union with the Thames to the 14th lock, is 114 feet 2 inches. The Paddington canal branches off from the former near Cranford; it is intended to carry it from the Paddington to the Thames, near the London docks. There are no minerals in Middlesex, though some curious geological specimens have been found in different parts, especially in Highgate Hill, when the archway was formed.

The vicinity of the metropolis has broken down any large estates that might have formerly existed in this county, as well as given a particular direction to the mode of farming, and the general employment of the ground. Farms in general are small; and the greater part of the county is in meadow, pasture, or garden and nursery-grounds. Corn is an article that can easily be conveyed from any distance, whereas hay, and particularly milk, must be procured for a large town from its immediate vicinity. From the operation of these causes, as well as from the soil in the greater part of Middlesex being better adapted for pasture than corn, it cannot be regarded as an arable county; the land in tillage being calculated only at about one-fifth of the whole, and what is under the plough is not well managed: indeed it cannot be otherwise in a district where the common-field system is so extensive—the common fields containing even yet nearly 20,000 acres; and the commons being much more numerous and extensive than might have been supposed so near the metropolis. The smallness of the enclosures too, (when the arable land is enclosed,) and the great number of trees in the hedge-rows, are much against good and profitable tillage husbandry: but perhaps the chief cause of the inferiority of Middlesex in this respect, must be sought after in the greater profit derived from dairy land, and garden and nursery grounds.

So long ago as the reign of Elizabeth, the soil in the north of the county, especially between Heston and Harrow, was famous for the fine quality of its wheat; but at present the wheat of Middlesex is by no means equal to that of Essex, Herts, or Kent; and, according to Mr. Middleton, there are not above 7000 acres cultivated with this grain. It is sown after beans, pease, tares, clover, or potatoes, in October, November, or December, and is reaped early in August, with a large toothless hook, in the manner called *bagging*, by which means the straw, which brings a very high price in London, is cut very close to the ground. The average produce of the county does not reach three quarters the acre. Rye is seldom cultivated, except for the purpose of being cut as green food in the spring. There is not much barley grown in Middlesex; indeed the soil in many parts is too strong for this species of corn; the number of acres is calculated at about 4000; it is usually sown after wheat or turnips; in the former case, as might be expected, the produce and quality are indifferent; in the latter case, on the sandy loams, they are both good. There are also few oats grown, though on the strong loams their cultivation might be introduced with advantage and profit. The Tartarian oat is usually sown; both oats and barley are mown, except where they are very short, when they are cut with a sickle. Beans are grown on the strong soils in the north and north-west of the county, to the extent perhaps of 3000 acres; in many parts they are dibbled; in others sown broadcast; in the former case, they are kept very clear by hand-hoeing, and the produce is good, as well as the land left in excellent condition; in the latter case, the produce is light, and the land left foul. They are seldom ripe till the beginning of September, when they are bagged like the wheat. Pease are grown extensively, especially on the rich light loams, in the low part of the county; white pease are sown for podding, while green, for Covent Garden market. They are always drilled, and being kept clean, are a very profitable crop. These pease are often sold by the acre, and in all cases, about 40 women and children are employed to pod 10 acres, who are paid either by the day or by the acre, or the quantity gathered: they are gathered into a sack of four heaped bushels. They are delivered to the salesmen in the market from three to five in the morning. The ground is usually picked twice over. The grey pease are suffered to stand till ripe, when they are cut with hooks and rolled into wads. Nearly all the kinds of grain are thrashed with the flail, there being very few thrashing-mills in the county. There are not many potatoes grown in Middlesex; in the north of the county the soil is too strong, and in other parts the crops raised for Covent Garden market are more profitable than potatoes would be. Besides, from the quantity of manure put on the ground, and the slovenly and imperfect manner in which they are cultivated, the quality of the potatoes grown near London is very indifferent. The culture of tares is extending fast, principally as green food, and as a preparation, on stony land, for a crop of wheat. Much of the soil of the county is not fitted for turnips, and even where it is, they are not cultivated so extensively, nor in such perfection as they ought to be. Many are grown for Covent Garden market, and not a few are sold to the cow-keepers. In 1817, owing to the scarcity of turnips, there were instances of cow-keepers giving fifteen guineas an acre for turnips, at the distance of sixteen miles, and being at the expence of pulling them and sending for them. Nothing strikes a stranger more than the immense waggon loads of turnips drawn by six stout horses going to Covent Garden market.

The meadow and pasture husbandry of Middlesex, though better than its arable, is yet very imperfect. Some of the meadows are very rich, especially those on the banks of the Lea; cattle are put upon them from August to April, after which they are shut up for hay. The fertility of these meadows arises partly from the natural fertility of the soil, and partly from their being flooded in winter, and artificially watered in summer. There are also excellent meadows on the banks of the Thames, especially between Chelsea and Fulham, and on the banks of the Coln, from Staines to Harefield. The whole extent of all these meadows is about 2500 acres. The richest grass, however, in the county is in the marsh land of the Isle of Dogs: in it there are about 1000 acres, which lie so low that they would be overflowed by every tide, were it not for embankments. The ground is divided by ditches, by means of which the water is carried off at low tide into the Thames, and thus the pasture is kept dry. It is calculated that there are nearly 18,000 acres of upland meadows and pastures in Middlesex, great part of which bears the marks of having been formerly arable. The soil varies from a poor loam, lying near the gravel, to a rich loam of considerable depth. Great quantities of manure are annually put on these grounds, especially in the immediate vicinity of London, and yet the produce, in respect to quantity, is very inconsiderable; they are pastured till November, or later, if the weather is open and dry, and afterwards shut up for hay. All the meadow land near Islington, Paddington, &c. is in the occupation of the cow-keepers, who mow it frequently two or three times a-year, as their object is to have hay of very fine quality. There is very little land entirely used as pasture. Middlesex has long been famous for its mode of making hay, and certainly the hay is got in with more of its sap in it, and with less labour, than in any other part of England. It is all mown by the acre; each man mowing from $1\frac{1}{2}$ to 2 acres a-day: five hay-makers, men and women, are provided for each mower; every part of the operation is carried on with forks, except clearing the ground, which is done with rakes. The whole time employed seldom exceeds four days: the first day it is spread, turned twice, and raked into rows, and put into small cocks; the second day it is again spread, and shaken into plats of five or six yards diameter, which are turned, and then formed into larger cocks than the first day. On the third day, the hay is put into a state to be carried, and sometimes, indeed, is carried on this day; on the fourth day, unless the weather is very unfavourable, it is always carried. The hay stacks in Middlesex are very neatly made, and well secured. In some parts it is put into barns capable of holding from 50 to 100 loads. No cattle are fattened in this county, but a very large number for supplying London with milk. The cow-keepers in general live at Islington, Hackney, Paddington, &c. They breed very few cattle, generally buying them when three or four years old, and in calf. They are the short horned Poldernesse breed. They are confined in stalls during the night; about three in the morning, grains are given them; from four to half past six they are milked by the milk-dealers, who contract with the cow-keepers for the milking of a certain number of cows; they are afterwards fed with turnips and hay; at eight o'clock put into the cow-yard; at twelve confined to their stalls, and grains given them; and at half-past one they are again milked. In the county of Middlesex there are upwards of 7500 cows kept for supplying London with milk. The quantity given by each cow, on an average, is supposed to be nine quarts a-day, or 3285 yearly. The cow-keeper finds the men who attend to the cows; the cow-dealer the persons who milk them. Every cow-house is provided with a milk room, where the milk is measured, and openly mixed with water from a pump.

The market-gardens in Middlesex are of great extent. They are of three kinds; the fruit, kitchen, and nursery gardens. The first are principally situated between Kensington and the western extremity of the county, and chiefly in the parishes of Chelsea, Fulham, Brentford, Isleworth, and Twickenham. The fruit gardens have two crops growing at the same time on the same ground viz. apples, pears, cherries, &c. which form an upper crop; and raspberries, currants, herbs, &c. which form an under crop. The management of these gardens is, in general, excellent; a wonderful degree of labour and skill are bestowed upon them; and their produce is proportionally lucrative, being calculated to average upwards of £100 per acre. There are upwards of 3000 acres under this cultivation, and they are supposed, during winter, to require five persons per acre, and in summer 10 persons. In summer, a great many Welsh women come up to labour in them. By far the richest kitchen-garden ground in Middlesex, and perhaps in the whole kingdom, is situated in the parish of Chelsea, and the adjoining part of Westminster near the Thames, called the neat-houses. The soil is a rich black loam, evidently formed by deposits from the river, which is here indeed kept off the ground by embankment. In dry weather, these gardens can be watered from the Thames by means of sluices; and their fertility is further secured and increased by at least 60 cart loads of dung laid on each acre annually. All kinds of vegetables are grown here, but chiefly those which, early in the season, bear a high price. The total annual produce is calculated at £250 an acre. The farming gardeners, as they are called, from working their land with the plough, are situated at a much greater distance from London; the crops they cultivate are principally pease for foddering, and turnips, cabbages, carrots, &c. for Covent Garden market. The most extensive and celebrated nursery grounds are either in the west of London, at Chelsea, Brentford, Kensington, Fulham, and Hammersmith, or to the north-east at Hackney and Dalston; there are also some at Bow and Mile-end, &c. No sight more rich and beautiful can be well conceived, than the collection of rare flowers which are to be seen in many of these gardens, and the hot-houses attached to them; and every improvement that ingenuity and science can produce, and capital execute, is to be met with, to bring the plants to the highest state of perfection. Every kind and variety of fruit tree, also, that can be cultivated in this country, is to be found in these nursery grounds. The hedge-row timber in this county, has also been mentioned as abundant; but the natural woods are very trifling, and are constantly decreasing, and scarcely any timber is planted. On the banks of the Thames, and the small islands in that river, between Staines and Fulham, a very considerable profit is made by the cultivation of osiers for the basket-makers.

In describing the cow-farms, the breed of cattle kept on them has been mentioned; there are few others kept, except on the pleasure grounds of gentlemen. Indeed the quantity of live stock in Middlesex is probably less than in any other county, in proportion to the number of acres. Few sheep are kept, and those principally for breeding house and grass lamb. The farm-horses are of a large size, of the Leicestershire breed. At the time when there were more distilleries in the county than there are at present, many hogs were kept and fattened at them; but now there are comparatively few in Middlesex.

There are few manufactures, except in London and its immediate vicinity; and these have been noticed in our account of the metropolis. In this article, however, it may be proper to notice more particularly the manufacture of bricks. These are made in all directions round London, but chiefly from the strong loam near Islington, Kingsland, and Hackney. Upwards of 2000 acres have been dug to the depth of from 4 to 10 feet for brick earth; and each acre is calculated to have paid, on an average, £4000. The sum usually paid to the owner of the soil for an acre is £100. The brick earth is mixed with coal ashes and sand; and the bricks are burnt partly by the ashes they contain, and partly by ashes strewed among the layers of bricks in the kiln. Gravel is another very profitable article derived from the ground, it being the material exclusively employed in making and repairing the roads; hence they are very dusty in summer, and very deep and heavy in winter; and were it not that the county is so flat, they would be very inconvenient for carriages and waggons. Middlesex is intersected by the three most frequented turnpike roads in the kingdom, namely, the great western road, the great northern road, and the road into Essex, Suffolk, and Norfolk. The following are the results of the last return to Parliament on this subject, for the year 1814.

	Miles.
Length of paved streets and turnpike roads, - -	304
Length of all other highways on which carriages go, -	667
Total,	971

Estimated value of the labour employed in these roads,	£3045
Composition money - - - - - -	11713
Money expended in law-suits, &c. - - -	466
Total,	£15224

or at the rate of about £100 a mile.

Besides the London markets, the principal markets in Middlesex are at Uxbridge, Barnet, Hounslow, &c. That at Uxbridge is one of the greatest corn-markets in the kingdom; and that at Hounslow generally presents a considerable number of fat cattle.

The following are the results of the last returns to Parliament, respecting the poor rates and other parochial rates of this county, for the year 1815.

Annual value of real property in 1815 -	£5,595,536	0	0
Poor and other parochial rates - - -	675,167	0	0
Average rate in the pound - - - -	0	2	5
Money expended in the maintenance of the poor	505,601		
Money expended in suits of law, removals, &c. -	24,099		
Money expended for militia purposes - - -	10,258		
Money expended for church-rates, county-rates, &c.	153,396		
Total money expended - - - -	£693,354		
Number of poor supported out of workhouses -	18,241		
Number of poor supported in workhouses -	16,026		
Number occasionally in and out of workhouses -	83,988		
Total - - -	£118,255		
Members of friendly societies - - -	£67,186		
Amount of charitable donations for parish Schools -	£6,251		
Amount of charitable donations for other purposes,	17,447		
Total - - -	£23,698		

On an average of three years, viz. 1813, 1814, and 1815, it appears that out of 207 parishes or places, 177 maintained the greater part of their poor in workhouses; that 12 in every 100 of the population were relieved; that the rate amounted to 13s. 11d. per head; and that the average expence of keeping each pauper amounted to £4, 9s. 5d. annually; that $\frac{1}{28}$th of the money raised is expended in rents of land—$\frac{1}{43}$d for the militia; the total, independent of the poor, between $\frac{1}{3}$d and $\frac{1}{4}$th; and that $\frac{1}{3}$d in every hundred were members of friendly societies. The following comparative details are also important:

	Parochial Rates.	Expended for Poor.
In 1776, - - -	£89,108	£79 090
Average of 1783-4-5, -	102,874	89,383
In 1803, - - - -	490,144	349,200
Average of 1813-14 15, -	663,103	517,300

The members of friendly societies in 1803, were more numerous than in 1815; in the former year there having been 72,741, whereas in the latter there were only 67,186.

The following are the results of the last returns respecting the population. In the year 1700, there were 624,200; in 1750, there were 641,500; in the year 1801, 845,400; and in the year 1811, 953,276, or 3380 persons in a square mile. There is one baptism to 40 persons; one burial to 36; and one marriage to 94. The following table exhibits the baptisms, burials, and marriages, from 1801 to 1810 inclusive.

	Baptisms.	Burials.	Marriages.
Males -	115,237	105,195	
Females -	114,174	101,609	100,774
Total	229,411	206,804	100,774

Houses inhabited in 1811 - -	130,613
Families occupying them - -	222,010
Houses building - - - - -	2311
Houses uninhabited - - - -	4326
Families employed in agriculture - -	9038
Families in trade - - -	135,398
All others - - - -	77 524
Males - - - - -	434,633
Females - - - - -	518,643
Total - - -	953,276
In 1801 - -	845,400
Increase - - -	107,876

See Middleton's *Survey of Middlesex*; Lyson's *Environs of London*. (w. s.)

MIDDLETON, Conyers, an eminent English divine, was born at York, in the year 1683. His father, the Rev. William Middleton, rector of Hinderwell, near Whitby, gave him a liberal education, and at the age of seventeen, he was admitted a pensioner of Trinity College, Cambridge, and two years after he was chosen a scholar on the foundation He took his degree of A. B. in 1702, and officiated as curate of Trumpington, near Cambridge. In 1706, he was elected a fellow of his college, and next year he became A. M. About two years afterwards, he married Mrs. Drake, a widow of ample fortune; and, after his marriage, he took a small rectory in the Isle of Ely, which he resigned, however, in little more than a year, on account of its unhealthy situation.

When George I. visited the university of Cambridge, in the month of October 1717, Middleton, along with several others, was created a doctor of divinity by mandate; and he took an active part in the famous proceeding against Dr. Bentley, which for some time occupied much attention. In that controversy, in the course of the year 1719, he published the following four pieces: 1. "A full and impartial Account of the late Proceedings in the University of Cambridge against Dr. Bentley," &c. 2. "A Second Part of the full and impartial Account," &c. 3. Some Remarks upon a Pamphlet, entitled, the Case of Dr. Bentley farther stated and vindicated," &c. 4. "A true Account of the present State of Trinity College, in Cambridge, under the oppressive government of their master, Richard Bentley, D. D."

When, in 1720, Dr. Bentley published his "Proposals for a new Edition of the Greek Testament, and Latin version," Middleton, the following year, published "Remarks, paragraph by paragraph, upon the Proposals," &c. Bentley defended his Proposals against these Remarks, which, however, he did not ascribe to Middleton, but to Dr. Colbatch, a learned fellow of his college, and casuistical professor of divinity in the university, for the double purpose, it is supposed, of giving him an opportunity of abusing Colbatch, and of shewing his contempt of Middleton. At a meeting in February 1721, the vice-chancellor and heads of the university pronounced Bentley's book to be a most scandalous and malicious libel; and they resolved to inflict a proper censure upon the author, as soon as he should be discovered. Middleton then published, with his name, an answer to Bentley's defence, entitled "Some farther Remarks, paragraph by paragraph," &c. These two pieces against Bentley are written with great acuteness and learning.

Upon the great enlargement of the public library at Cambridge, the office of principal librarian was conferred upon Dr. Middleton, who, to shew himself worthy of it, published, in 1723, a small piece with the title, *Bibliothecæ Cantabrigiensis ordinandæ quædam, quam domino procancellario senatuique academico considerandam et perficiendam, officii et pietatis ergo proponit.* In the dedication of this tract to the vice-chancellor, in which he alluded to the contest between the University and Dr. Bentley, he made use of some incautious expressions against the jurisdiction of the Court of King's Bench, for which he was prosecuted, but dismissed with an easy fine.

Soon after this publication, he had the misfortune to lose his wife, and having fallen himself into bad health, he undertook a journey through France and Italy, along with Lord Coleraine, and arrived at Rome early in 1724. He was at Paris towards the end of the year 1725, and arrived at Cambridge before Christmas. Shortly after, he published a tract, entitled *De medicorum apud veteres Romanos degentium conditione dissertatio; qua contra viros celeberrimos Jacobum Sponium et Richardum Meadium, servilem atque ignobilem eam fuisse ostenditur;* which drew upon him the displeasure of the whole medical faculty, particularly of Dr. Mead. Middleton defended his dissertation against various attacks in a new publication, entitled *Dissertationis, &c. contra anonymos quosdam notarum brevium, responsionis, atque animadversionis auctores, defensio, Pars prima.* 1727. Mead and Middleton afterwards became very good friends. A *pars secunda*, however, was actually written, and printed for private circulation, after Middleton's death, by Dr. Heberden, in 1761, 4to.

In 1729, Middleton published "A letter from Rome, shewing an exact conformity between Popery and Paganism; or, the religion of the present Romans derived from that of their Heathen ancestors." In this letter, he gave offence to some of the English divines, by attacking the Popish miracles with that general spirit of scepticism and levity, which seemed to condemn all miracles. In the second edition, he endeavoured to obviate this objection, by an express declaration in favour of the Jewish and Christian miracles. To the fourth edition, which came out in 1741, 8vo. were added, 1. "A prefatory discourse, containing an answer to the writer of a Popish book, entitled "The Catholic Christian instructed," &c. and 2. "A Postscript, in which Mr. Warburton's opinion concerning the Paganism of Rome is particularly considered."

Upon the publication of Tindal's famous book, called "Christianity as old as the Creation," many writers entered into controversy with its author; and, among others, Waterland, who wrote "A Vindication of Scripture," &c. Middleton, being displeased with Waterland's manner of vindicating Scripture, addressed "A Letter" to him, in 1731, containing some remarks on it, together with the sketch or plan of another answer to Tindal's book. He did not, however, put his name to the tract; nor was it known for some time, who was the author of it. Waterland having continued to publish more parts of "Scripture vindicated," &c. Pearce, bishop of Rochester, took up the contest in his behalf; which drew from Middleton "A Defence of the Letter to Dr. Waterland against the false and frivolous cavils of the author of the Reply," 1731. Pearce replied to this defence, and treated Middleton, as he had done before, as an infidel, or enemy to Christianity in disguise. Middleton, who was now known to be the author of the Letter, was, in consequence, very near being stripped of his degrees, and deprived of all his connections with the University. But this was deferred, upon a promise that he would make all reasonable satisfaction, and explain himself, if possible, in such a manner as to remove every objection. This he accordingly attempted to do, in "Some Remarks on Dr. Pearce's Reply." He also published, in 1733, "Some Remarks," &c. on an anonymous pamphlet, entitled "Observations addressed to the author of the Letter to Dr. Waterland," which was written by Dr. Williams.

During this controversy, Middleton was appointed, in December 1731, Woodwardian professor, being the first appointed by Woodward's trustees. In July 1732, he published his inauguration speech, with this title, *Oratio de novo physiologiæ explicandæ munere, ex celeberrimi Woodwardi testamento instituto habita: Cantabrigiæ in scholis publicis.* This situation, however, he resigned in 1734, when he was made principal librarian.

In 1735, he published "A Dissertation concerning the origin of Printing in England," &c. in which he endeavoured to prove that this art had been introduced by Caxton. In the year 1741, appeared Middleton's great work, "The History of the Life of M. Tullius Cicero," in 2 vols. 4to. The profits of this work enabled him to portion two nieces, and to purchase a small estate at Hildersham, about six miles from Cambridge. In 1743, he published "The Epistles of M. T. Cicero to M. Brutus, and of Brutus to Cicero," &c. in which he vindicated the authority of these epistles against the objections of the Rev. Mr. Tunstall. In 1745, he published *Germana quædam antiquitatis eruditæ monumenta, quibus Romanorum veterum ritus varii, tam sacri quam profani, tum Græcorum atque Ægyptiorum nonnulli, illustrantur*, &c. 4to.; and in 1747, "A Treatise on the Roman Senate," in two parts.

In the last mentioned year also, a publication appeared, which laid the foundation of another controversy with the clergy. This was his "Introductory Discourse to a larger book, designed hereafter to be published, concerning the miraculous powers which are supposed to have subsisted in the Christian church from the earliest ages, through several successive centuries," &c. This introductory discourse was immediately attacked by two celebrated controversial writers, Dr. Stebbing and Dr. Chapman; and Middleton replied by "Some Remarks" on both their performances. In December of the same year, he published his larger work, with this title, "A Free Inquiry into the miraculous powers which are supposed to have subsisted in the Christian Church," &c. Innumerable antagonists now appeared against him, among whom Dodwell and Church distinguished themselves so much, that they were complimented by the University with the degree of D. D.

Meanwhile, Middleton surprised the public with "An Examination of the Lord Bishop of London's Discourses concerning the use and intent of Prophecy," &c. which was refuted by Dr. Rutherforth, divinity professor at Cambridge. While meditating an answer to all the objections made against the "Free Inquiry," he was seized with a slow hectic fever and disorder in his liver, which terminated his life, at Hildersham, on the 28th of July, 1750, in the sixty-seventh year of his age. He left no children by any of his wives.

In 1752, were published the miscellaneous works of Middleton, containing all those above mentioned, with the exception of the Life of Cicero, and several tracts which had not been published during his life. A second edition of these miscellaneous works was afterwards published in five volumes octavo.

Middleton was undoubtedly a man of great talents, learning, and industry; and in controversy he was a very formidable antagonist. But neither the principles he proposed, nor the style and tone of his polemical tracts, do much credit to his judgment and temper. None of his works are now much read, except his Life of Cicero, which is certainly a very valuable production, although written too much in the language of panegyric. (z)

MIDWIFERY.

Midwifery strictly signifies the art of delivering women; but it is now universally understood to include also the physiology and pathology of the pregnant and puerperal states, and a knowledge of the management of infants and children, both in health and disease.

The term, in the English language, is derived from the two Saxon words signifying *mead* and *wife*, the midwife being the woman who got a present or gift for accomplishing the delivery. The old Scotch term for midwife is *howdie*, supposed to be derived from the Saxon word signifying childbirth.

The French name their midwives, from their reputed skill, *sages femmes;* whilst the art itself is styled, from the confinement of the patient, *L'art des Accouchemens.* In all ages, and in every country, the practice has been generally in the hands of females; and both in ancient and modern language the appellation of the practitioner is always feminine, with the exception of the French term *accoucheur.*

By the Roman law, midwives were recognised as a distinct class in society, and partook of certain immunities and advantages in common with medical practitioners. At the present time, in several continental countries, no one can practise midwifery without a license; but in Britain it is otherwise, as every one who chooses to run the risk incurred by common law for the fruits of ignorance, may practise as a midwife. With regard to accoucheurs, they stand in this peculiar state, that they sometimes are considered as belonging to medicine, and sometimes to surgery. With the exception of a temporary measure adopted by the College of Physicians in London, no public body has issued distinct licenses to male practitioners. In some German universities, it is explicitly attached to the united degree of doctor of medicine and surgery. In others, it seems indifferently to belong to the doctor of medicine or master of surgery. In the university of Glasgow, the only one in Britain which confers surgical degrees, the right to practise midwifery is included in the degree of magister chirurgiæ.

Historical Sketch of the Progress of Midwifery.

It would be quite impossible, in a work of this kind, to trace the history of midwifery minutely through every individual who has written on the subject, from Hippocrates downwards. Even to a medical reader, this would be more a matter of curiosity than utility. It appears from the early writers whose works we possess, that in natural labour the patient was placed on a particular kind of seat or stool, and the process of delivery conducted altogether by the midwife, who, we may presume, from little being said of her duty, had no very difficult office to perform. It was only in cases of protracted labour, or in those where the child could not be born, either on account of its position, or size compared with the pelvis, that the male practitioner was called; and at this place it may be observed, that Paulus Ægineta, in the 7th century, seems to be the first who was styled a man midwife. The practice adopted in such cases, no doubt varied a little at different times, and in different hands; but the general principles of conduct were not much diversified, and may be learned by consulting the works of Ætius, Albucasis, and Avicenna. In tedious labour, the effect of concussion was sometimes tried to promote delivery; but it was more common to employ means for producing relaxation, such as emollient applications, and even the warm bath. Bloodletting, so useful in many cases of tedious labour, was strongly recommended by Hippocrates; and it is much to be regretted, that his authority in this respect has been so long slighted by the moderns. Those, on the other hand, who seemed to be too much enfeebled, were ordered to be sprinkled with vinegar, or to sit over vapours supposed to have a strengthening quality.

In preternatural positions, the presentation was either pushed back, and the head made to come forward; or, the protruding member was twisted off, and the child pulled away piecemeal. When the head was large, or the pelvis small, various modes were adopted. The head, by some, was pushed back, if not impacted, and the child turned, so as to allow the practitioner to deliver by the feet. This continued long to be the resource in all cases where it was practicable, as there was thus a possibility of saving the child. But if the obstacle were considerable, the infant always perished, and, in many cases, the body was actually torn away from the head. This accident in aftertimes gave rise to different contrivances for extricating the head which thus remained in the uterus. Other practitioners, at a very early date, endeavoured to deliver the child by fixing a fillet or band around the head, thereby becoming able to pull it down. In a greater number of instances, however, they accomplished delivery by opening the head, or fixing a hook or crotchet into it, or squeezing it in forceps furnished with teeth.

From the seventh down to the sixteenth century, various writers are to be met with, but little improvement is to be found in the art. The most popular work in the sixteenth century, was published originally in German by Eucharius Roesslin, commonly called Rhodion. This, which was entitled the *Garden of Lying-in Wo-*

men and Midwives, was translated into Latin and all the modern languages, and became the code of instruction for midwives. It was not possible for rapid improvement to be made, the women could not go beyond their teachers, and their teachers had few means of instructing themselves by actual practice. Dr. Veit, in 1522, was publicly branded in Hamburgh, for having been present at a delivery under the disguise of a midwife.

In the sixteenth century, when little originality was to be met with, Ambrose Paré formed an exception to the general character of the age; and it is this circumstance which has made him stand higher in public estimation than his real merits deserve. Yet it is far from the intention of the writer of this article to detract from his claim; for surely the man, who, in an age of darkness and servitude, can to any degree desert the beaten path for a better way, is entitled to more praise than the author of a brilliant system in a period enlightened by science and philosophy. Paré was the best surgeon of his day, and his book, in many respects, bears the same relation to medical details that Froissart's chronicle does to a dry history. His obstetrical directions are to be found in his general work, but came again before the public in a separate form by his pupil Guillimeau. This contained a view of all that was known at the time; but its chief merit, and the ground of Paré's obstetric reputation, is the rule, which he rendered nearly absolute, in all preternatural labours to turn the child, and deliver by the feet. This work was succeeded, in 1668, by a system of F. Mauriceau, who not only had much private experience, but opportunity of improvement in the Hotel Dieu, part of which by this time had been appropriated to lying-in women, and is to be considered the first establishment of the kind in Europe. His book is not only worthy of notice from its merit, considering the time when it appeared, but also from the English translation by Dr. Chamberlain, containing an intimation in the preface that his father, himself, and his brother, possessed a mean of delivering women in difficult labour in a way compatible with the safety of the child. How long his father or the family had possessed the secret is not known, but the first public intimation is given in the preface alluded to, which appeared in 1672 Before this he had gone over to Paris with the intention of selling his secret, but imprudently boasted that he could deliver safely a woman whom Mauriceau had declared could not be saved otherwise than by the Cesarean operation. The result of his trial, in this case, was such as might have been expected, and, instead of selling his secret, he, by promising too much, lost his reputation, and with empty pockets returned to England. Next he went to Holland, where he communicated at least part of his secret to Roger Roonhuysen, from whom it passed to Ruysch and others as a nostrum; nor was it revealed till 1753, when De Vischer and Van de Poll purchased it, and made it public. It was long afterwards in repute under the name of the Lever; but has now deservedly lost ground. It would appear that Chamberlain used both the lever and the forceps; but whether he only revealed the former to Roonhuysen, or had not then employed the forceps, is uncertain, and unimportant in the annals of quackery. Of late, a discovery has been made of the original instruments, in an old building in Essex, where, in the floor of a closet, a door was perceived with hinges. This being opened—not by Mrs. Radcliffe, but by a sober matter-of-fact-man—there was found neither blood-stained armour, nor mysterious parchment, but some rusty instruments of three different descriptions, a lever and two pair of forceps, one a little more improved than the other. Soon after this time, other practitioners, both in Britain and on the continent, employed similar instruments; but it was not for many years afterwards that a description of them was made public. Dr. Denman, in a very desultory historic sketch which he prefixed to his work, and which is altogether unlike that work, says, that Dr. Chapman first described the forceps in the *Edinburgh Medical Essays*, in 1733; but he cannot have read these essays, for it is Mr. Butter who there gives a plate of the instrument he had seen in Paris, whilst in the end of the volume Chapman is criticised for not depicting his forceps. This he afterwards did. He is reported to have been the second person who taught midwifery in this kingdom. Maubray, about ten years before, had started for the first time as a lecturer; but is chiefly known for his opposition to the use of instruments.

Soon after Chapman taught, Dr Smellie came forward, and gained deserved reputation both as a practitioner and teacher. He published, 1752, a system, which, although unimportant now, was long the elementary work consulted by all students, and to this he afterwards added two volumes of cases, and one of plates. He gave distinct rules for using the forceps, which he improved in their construction. He did not, however, carry their utility far enough; for he is found still advising the old mode of turning when the head is not fixed. In his class he made considerable use of machines; and, if we may credit his enemy Dr. Douglass, he endeavoured to condense his information, so as to suit all purses as well as all capacities; for he is said to have hung out a paper lantern with these words, "Midwifery taught here for five shillings"

About the same time, Levret, in Paris, acquired high reputation, not only for his description and improvement of the forceps, but for his general knowledge of midwifery. His observations on uterine hemorrhage, considering the state of science at the time, are admirable and important. Accoucheurs have made a distinction of floodings into those arising from detachment of the membranes, or part of the placenta which is properly situated, and those produced by the placenta being attached in a greater or less degree to the os uteri. In the former case, Puzos advised the membranes to be ruptured, in order to excite contraction of the womb. In the latter, Levret decided that nothing but delivery could be useful. By blending these two works, Rigby afterwards compiled a treatise on the subject; but the opinion now of every judicious practitioner is, that in all cases of flooding requiring manual interference, that ought to consist in delivering as soon as it can safely be accomplished. This is a subject of very peculiar importance, and it is necessary that the practitioner make himself well acquainted with the principles of conduct, and act with promptitude and decision.

Dr Hunter appeared also on the field about the same time; for he came to London in 1741 His talents, his general learning, his professional knowledge, his zeal and industry, together with a good manner, introduced him into extensive practice. His obstetrical works consist of the anatomy of the gravid uterus, illustrated with very splendid plates, and a description of the retroversion of the womb. He added to his anatomical lectures a few on midwifery, which, it is much to be feared, have done essential injury to the profession and the community. Patience was his advice in most cases, and an almost unbounded reliance on the power of nature formed the basis of his practice. That much good sprung from his admonitions to avoid irritation, and the use of stimulants in natural labour, is unquestionable. But it is equally true, that, when assistance is necessary, patience becomes another name for negligent procrastination. It is not to be credited how many women and children are lost by too great reliance on the power of nature, and a reprehensible delay in having recourse to the assistance of art; and with the highest respect for the memory of Dr. Hunter, the writer of this article remains convinced, that his authority contributed greatly to introduce and support that passive conduct which is too often pursued in protracted labour. The directions of the late Dr. Osborn on this subject, which sprung from the school of patience, cannot be read without astonishment, and the deepest regret; and the consequence of this system of delay is and must be, that in many instances, although the child be at last expelled, it is born dead, and the mother soon follows; or instruments are at last used, when they are less likely to save both parties than if they had been employed earlier, whilst, in all, the patient suffers more pain by this supine conduct, than she would have done by more vigorous practice.

It unfortunately happens, that in some instances the pelvis is so contracted or deformed, that by no method can a living child be brought through it. In such cases four different methods have been proposed: 1*st*, To open the head, and fix a hook or crotchet on it, and then draw down the child. 2*d*, To make an incision through the skin and muscles into the womb, and thus extract the child alive. This is called the Cæsarean operation. 3*d*, To divide the joining of the bones of the pelvis in front, and thus endeavour to enlarge the cavity through which the child must pass. 4*th*. To induce premature labour. It is not necessary to enter here into any critical examination of the comparative merits of these different methods. It may only be observed, that the chief point of controversy is, whether the crotchet or the Cæsarean operation should be preferred. In this country the former is always resorted to, when possible, and the latter is only performed in extreme cases. These, it may therefore be expected, can seldom prove successful; and, as if the condition of the patient were not a sufficient source of danger, it is seldom performed till she has been some time in labour, and perhaps considerably exhausted. This has arisen from the same cause which has been already so strongly reprehended. It surely may be early ascertained in such extreme cases, that the pelvis is too small to permit of delivery by any means through it; and delay, after this is known, is adding to the hazard of an operation which requires no additional risk to render it formidable. This delay has greatly arisen from the arguments and statements of the late Dr. Osborn, who maintained that no case of deformity so great could occur as would prevent the extraction of the child by the crotchet. In proof of this, he published a case where the operation proved successful in extreme contraction. The fallacy of his reasoning was very ably shewn by the late Dr. Hamilton, whilst Dr. Johnston experimentally proved, that it was impossible to bring a mutilated child through an aperture cut in a piece of wood exactly of the dimension of the pelvis described by Dr. Osborn, who consequently must have been deceived. It is of great importance to humanity to have this point ascertained; for, although every British practitioner prefers the crotchet to the Cæsarean operation, yet, if it be conceded that in some cases the former cannot be employed, it follows that in such cases the sooner we resort to the operation, the more likely it is to be successful. It has almost uniformly been fatal in this country, but often successful on the Continent. This must arise either from its being performed earlier there, or on more favourable subjects. If in this country we perform it only on the most deformed and unhealthy, it is our duty to these sufferers not to increase their danger by delay, in the senseless expectation of being able to accomplish a physical impossibility.

To carry this sketch of the progress of midwifery farther, or extend it to the diseases of women and children, would exceed the limits proper to a work of this kind. To notice all the eminent writers and teachers of the present day would be impossible, and to make a selection where so many are to be found, would be both difficult and invidious.*

---

* In noticiog the rise and progress of obstetric science in the United States of America, we have to mention with respect the name of Dr. William Shippen, who, after having enjoyed the advantages of a most liberal medical education in Europe, and sedulously cultivated anatomy, surgery, and midwifery, under the immediate direction of the celebrated Dr. William Hunter, upon returning to his native country, gave the first public lectures on these branches of medical science io Philadelphia, in the year 1762, and continued for many years to practice midwifery very extensively. His lectures on this subject, though few in number, may be said to have embraced the leading principles of the art, which he illustrated on a machine, probably the first of the kind which had ever reached these shores.

The science of obstetrics is now considered as a necessary part of medical education in this country, and is regularly and fully taught in the universities aod medical institutions in the United States, by professors appointed for that express purpose. Several interesting works on this branch of medical science have also been published by practitioners of respectability, tending much to the improvement of an art, which may be justly considered as essential to the prosperity of every community. We may be allowed to state, that the treatment of puerperal women generally, if the bills of mortality are to be relied on, has been more successfully conducted in the United States than in Great Britain.

In proof of this we may mention the ioformation from an intelligent author, (Dr. Merriman,) that on examining the bills of mortality in London, it appears that the average number of deaths in childbed, for ten years towards the close of the 17th century, was in the proportion of 1 to 39, while, for the same number of years, at the commencement of the present century, it was only in the proportion of 1 to 106.

But upon torning our attention to the United States, and particolarly to the "Statement of Deaths in the City and Liberties of Philadelphia," for the last eleven years, endiog the 1st of January, 1818, it appears that the number of women dying in childbed, when compared with the whole number of deaths, is only as 1 to 419.

It must notwithstanding be confessed that, not baving the London bill of mortality to refer to, there may remain some uncertainty, whether the deaths from puerperal fever are included under the head of *Childbed*, but even should that be the case, the number of deaths onder the heads of *Childbed* and *Puerperal Fever, taken conjointly*, and occurring for the last eleven years in Philadelphia, is only in the proportion of 1 in 178. J.

Part I.—OF THE PREGNANT STATE.

CHAP. I.

Of the Gravid Uterus.

The first visible change produced on the uterus and ovaria by conception, is increased vascularity. Simultaneous with this is an augmentation of the bulk of the womb, or enlargement of its cavity, and a secretion within that cavity. The cervix uteri is filled with inorganic jelly, whilst the fundus and body are lined with a coating consisting partly of lymph, and partly of vessels. This has been called the membrana decidua, and is formed before the ovum can be detected in the uterus. Whilst a receptacle is thus preparing for the child, changes are going on in the ovarium, where the ovum first appears. This becomes more vascular, and at one part a small vesicle becomes prominent. The exterior covering of the ovarium seems at this part to be absorbed, whilst the fimbriated extremity of the tube adheres firmly over it, and receives the vesicle or ovum, as it is extricated from the ovarium surface, conveying it down into the uterus itself, whence it is to be developed. That part of the ovarium whence the embryo has issued, undergoes certain changes in appearance, forming a distinct substance, known under the name of corpus luteum, the presence of which is considered as an indication of conception having at one period or other taken place. At a very early stage, several vesicles may be discovered under the covering of the ovarium, at least the writer has observed this in two or three instances, but whether these be ova which fade, is not determined. The ovum, from the earliest time when it can be examined, consists of two vesicles, one within the other. The innermost is much smaller than the outermost, but is connected with it at one spot. The internal contains a little transparent fluid, and the minute embryo. The space between the two vesicles is filled with clear jelly, like the vitreous humour of the eye, and the outer surface of the external vesicle is covered with small vessels, which in a short time increase so much that they form a distinct vascular covering, known under the name of the spongy chorion, whilst the vesicle they cover is called the membranous chorion: the vesicle within both is called the amnion, and the fluid it contains, and which is in immediate contact with the embryo, is named the liquor amnii. For a considerable time after the ovum enters the uterus, the chorion and amnion, except at one point, are far distant from each other, but presently the amnion enlarges more rapidly, so as to fill the space enclosed by the chorion, and the intervening jelly is absorbed in the same proportion. In common language, the embryo is said to be within these membranes, but anatomists know well that it is exterior, as the bowels lie without the peritoneum For it is next to be noticed, that at one part, namely, where the embryo is situated, a small prolongation of both membranes is turned inward, so as to form a short tube, along which vessels run from the spongy chorion to the embryo, and from the embryo to the chorion. This prolongation is afterwards called the umbilical cord, and the passing vessels the umbilical vessels. When the ovum enters the uterus, it does not pass down unconnected through the tube, nor fall loosely into the uterine cavity, but, arrived at the end of the tube, and entering the womb, it meets with the decidua vera, as it has been called, and an intermixture of vessels takes place between the chorion and decidua, and in proportion as the ovum expands and fills the cavity, the decidua expands or grows with it; affording a covering, until it grows so large as to fill the cavity. This expansion of the decidua has received the name of decidua reflexa, and it becomes thinner and more gelatinous as pregnancy advances. It has been already stated, that the embryo sends vessels which ramify over the chorion, and part of which there unite to the decidua reflexa; but at that part where they pass out from the embryo, they are more numerous than elsewhere, and unite with the decidua vera, and form a thick vascular cake called placenta, which consists thus of two portions, one formed by the womb, and one by the fœtus, and it serves as the intermedium between them, and the source whence nourishment is derived, and a substitute for the lungs in the fœtal circulation. To be more minute on this subject is not consistent with the plan of this work.

It is uncertain at what time the ovum enters the uterus. Dr Haighton could not detect it in the uterus of the rabbit earlier than from the fourth to the sixth day. Now, in that animal the period of uterogestation is only 30 days; from analogy, which doubtless is not to be held as proof, one would not expect to find it early in women, who go so much longer. Some microscopic observers have supposed that they saw the embryo eight days after conception; but, be this as it may, it cannot be detected with the naked eye for much longer. It is not probable that the ovum can be seen in the uterus until nearly three weeks after conception. In an instance where the conception could not be less than five weeks, the membranes were of the size of a small chesnut, and the fœtus scarcely so large as an ant. In the sixth week it is curved, forming a bulk like a split pea. In the seventh as large as a bee. In the eighth, about the size of an ordinary bean. At first the embryo consists merely of two oval bodies joined together, which are the rudiments of the head and trunk; then the extremities sprout out like buds, and the different organs become gradually developed. At the full time a male child measures about twenty inches, and the average weight is seven pounds.

At first, from the increased weight, the uterus subsides in the pelvis, at the same time that the os uteri becomes more circular, instead of transverse, as formerly. In course of time, however, it becomes so large that it can no longer remain sunk in this situation, but rises above the brim of the pelvis. The time at which this happens must depend to a certain degree on the capacity of the pelvis, and the enlargement of the uterus It usually happens in the end of the fourth month, that is, after 16 weeks from conception, but it may be earlier, and is often somewhat later. This elevation takes place in general rather suddenly, and in many cases the sensation occasioned by the rising of the uterus is very well marked, and sometimes accompanied with fainting, or hysterical symptoms. This is confounded by many with the motion of the child itself, which is felt about this time, and the person is said now to quicken. It is quite absurd to suppose, that before this the child is not alive, and does not move. The motions are now felt, because the child is stronger and larger, compared to the quantity of liquor amnii, and the uterus is in a more sensible situation. Lawyers, however, who are in general bad physiologists, have decided that it is murder to procure abortion after the time of quickening, but a minor offence to do so earlier. If any doubts have existed respecting the existence of pregnancy, they are at this period cleared up; for the patient herself is sensible of the motion, and the accoucheur, by examination *per vaginam*, feels the uterus to be heavy, and when pressed up with the finger, there is perceived the *mouvement de ballotement:* and by gently striking the under part of the uterus once or twice, the fœtus is perceived distinctly to move or flutter within.

It requires nine months to bring the human fœtus to perfection, and experience teaches many women, from particular feelings, how to judge pretty accurately with regard to the time when they are to be confined. When there is no particular circumstance to guide them, the general way is to calculate forty-two weeks from the last period of menstruation, forty weeks being the term of gestation. This determines within a fortnight, and farther assistance is derived from attending to the time of quickening. Many bring forth before the full time, but it is rare to go beyond the ordinary time; but it is certainly possible to do so.

Children born in and after the seventh month may live, but the nearer they approach to perfection, the more likely are they to thrive. If they have no hair nor nails, and the skin be not red about the palms of the hands, breast, and scrotum, and if they can neither cry nor suck, there is no chance of their living. Instances, however, have occurred, where children in the sixth month have been kept alive, by being fed and kept warm.

CHAP. II.

Of the Signs of Pregnancy.

Although some women very early begin to have complaints, or to experience certain sensations which apprize them of conception having taken place, yet in general the first indication of pregnancy is the interruption of the menstrual action. It has been a question for discussion amongst medical men, whether the menses have ever continued to appear regularly during pregnancy, and, notwithstanding the different instances which have been brought forward to the author, he is still convinced that the two conditions are so incompatible with each other, that regular menstruation is inconsistent with pregnancy. It is placed beyond all doubt, that many women have had periodical discharges during part or the whole of pregnancy; but these, from the attendant circumstances, are rather to be viewed as hemorrhages than as a continuation of the natural secretion. Yet Baudeloque, Chambon, and other respectable men, have told us of instances, where women did not menstruate except during gestation.*

The breasts very early sympathise with the uterus. It is not unusual for them at first to become a little smaller, but by the third month there is an evident enlargement, and the nipple presently becomes surrounded with a brown areola. The augmentation of size is slower of taking place in those who are delicate, or who have sanguineous evacuations from the uterus during the early months of pregnancy. A serous or milky fluid also is secreted, and either flows from the nipples, or can be pressed out.

It is not unusual for the abdomen, soon after conception, to become flatter than formerly, and continue so for a month or two, after which it enlarges. In other instances it very early increases in size, chiefly from a distended state of the bowels. In pregnancy the tumour is most manifest below the umbilicus, which generally becomes prominent towards the sixth month, if not sooner.

It is possible, but not usual, for all these symptoms to appear in the virgin state, in consequence of uterine irritation; but much more frequently they arise, if not from true pregnancy, at least from a blighted ovum, or what has been called a false conception. Many women, who have had a large family, when they advance in life, are liable to inflation of the abdomen, and irregularity of the menstrual discharge, occasionally accompanied with slight changes in the appearance of the breasts. They are willing to believe themselves not past the age of childbearing, and fancy they feel the motion of the child; but it is only wind passing along the bowels, and is known to be so by shifting its place, and generally being perceived higher than the uterus.

These signs, with the existence of what have been called the disorders of pregnant women, do, in the married state, justly warrant the belief of the existence of pregnancy; but we cannot arrive at certainty until the time of quickening, or by examination *per vaginam*, about that period. Earlier, even this mode cannot positively decide the question, for the womb may be enlarged by other causes. Still it affords in the third month strong presumptive evidence.

CHAP. III.

Of the Disorders incident to the Pregnant State.

It is not to be expected that the uterus can undergo the great and active changes which it experiences after conception, without affecting to a greater or less degree the whole frame, and particular organs. The general sympathy which exists amongst the different parts of the body, as well as the particular influence which individual systems and viscera exert on one another, render it impossible for one part to have its action materially altered, increased, or diminished, without producing more extensive effects.

* In these cases, the secretion of the menstrual fluid is most probably from the cervix and the immediate vicinity of the os uteri, otherwise the ovum, in the early stages of pregnancy, must necessarily be detached and carried away by the discharge.

The effects produced by the gravid uterus may be classed under the following heads: 1*st*, Those which arise from the sympathy of particular parts with the uterus, some of which have their activity increased, others diminished. Examples of these we have in the changes produced on the breasts and stomach. 2*d*, Those which proceed from more general sympathy, as we see exemplified in the nervous and vascular systems. 3*d*, Those which are occasioned chiefly by a mechanical cause, as œdema of the feet, and swelling of the veins. Few, if any, of these effects, however, can be said to arise purely and entirely from one class of causes. They may be individually referable to one or other class chiefly, but the causes themselves are so interwoven and mixed up with one another, and there are so many reactions, that the classification must be taken with circumspection, and a latitude allowed.

From the brisk and increased action which goes on in the uterus, so long as gestation continues, and the ovum thrives, we find that a change takes place in the state of the blood. It does not assume an inflammatory appearance, but it becomes sizy, an effect not peculiar to pregnancy, but produced by many other local irritations. The arterial system is likewise excited, so that the pulse becomes sharper, sometimes stronger, and generally, in the commencement of pregnancy, variable. The functions dependent on the blood-vessels are also influenced; animal heat is often increased, the deposition of fat, and perhaps of other constituent parts of the frame, is either actually lessened, or the process of absorption is increased, or both of these take place; for in general the female becomes thinner. Yet there is rather a redundancy than a deficiency of blood, for plethora is apt to exist during pregnancy In many cases these effects appear only in a moderate degree; in other cases, however, the patient is actually feverish, sleeps almost none, and becomes extremely emaciated. As this condition, like the other disorders of pregnancy, arises from the state of the uterus, it is evident that, so long as the latter exists, the former must continue; and all we can do is, to mitigate what we cannot cure. This is best done by strict attention to the state of the bowels, taking occasionally the saline julep, avoiding much animal food, every thing of an irritating or heating nature, and even abstaining from all unnecessary quantity of the blandest liquids, sleeping on a firm matress, with no more bed-clothes than are requisite, procuring a free ventilation of air, and detracting blood from the veins, if the symptoms do not yield to this regimen. With regard to exercise, there has been some diversity of opinion; but all must agree, that where there is a tendency to abortion, this must be abstained from altogether, or taken in great moderation, till the period of danger be past. Where there is no cause, however, to forbid it, advantage is very evidently derived from regular, but moderate exercise, taken daily to such extent as does not occasion fatigue. It is partly from the opportunity of taking such exercise with facility, and partly from the salutary influence of pure air on the whole frame, that many patients experience great benefit from spending the period of pregnancy in the country, although inconveniences of a different nature may result from this practice. The stomach and bowels very early are affected by pregnancy, producing sickness, vomiting, heartburn, fastidious appetite, costiveness, or an opposite condition of the bowels, and a train of secondary symptoms ensuing therefrom. When these disorders are in a moderate degree, little requires to be done; and indeed some men of judgment have reasoned themselves into a belief, that, as they arise naturally from pregnancy, we ought not to be very solicitous in removing them. This principle, if followed up, would lead to most absurd as well as dangerous practices in medicine, and, in the present case, would, particularly with regard to costiveness, make us overlook, and indeed encourage a very decided cause of both distressing and formidable disease. Partly from the effects produced by the uterus itself on the nervous system, but still more decidedly by the state of the bowels during pregnancy, many hysterical and anomalous affections are produced, and irregular and painful actions excited in distant parts; and, from the same cause, the brain itself is acted on, and a determination of blood made to the head, which produces severe headaches, convulsions, or apoplexy itself. We are yet ignorant of much which relates to the mutual reaction of the nervous and sanguiferous systems, and perhaps overlook too much the agency of the spinal marrow in many of those severe disorders of the two systems, which have their origin in the state of the abdominal viscera. Nothing tends more to prevent those harassing and often dangerous symptoms, styled nervous, than rigid attention to the bowels. But experience and observation have taught the writer, that when these have actually taken place, particularly if attended with a sense of fulness in the head, much giddiness, or headach of an oppressive kind, or any degree of stupor, that the lancet is the mean chiefly to be trusted. Fashions are not confined to Bond Street, but prevail as much amongst physicians as milliners; and perhaps the present system is to trust too much to the efficacy of purgatives, and too little to the effect of blood-letting.

It is not meant to say that the common hysterical fits which may attack women about the early period of pregnancy, or at quickening, require the lancet, or that these fits, at any period, demand it, unless accompanied with much plethora. They may be overcome by purgatives, light diet, and antispasmodics, aided sometimes by tonics. But there is no fallacy more dangerous than the doctrine, that venesection is improper, merely because the complaint assumes the appearance of hysteria. There are few disorders in the pregnant state, which, when severe, are not relieved by bleeding, unless they evidently are dependent on a state of debility. The very sickness and vomiting of pregnant women are best relieved by this remedy, which subdues the excessive irritation of the stomach; or, if it fail, the application of leeches to the epigastric region is almost certainly beneficial; whilst a general plan is followed for the relief of a systematic condition, particular remedies must be employed for obviating special symptoms: thus heartburn must be removed by antacids, such as chalk or magnesia, combined with ammonia or soda; flatulent pains, by laxatives and carminatives, or antispasmodics; continued sickness, with bitter taste, by very gentle doses of calomel; convulsions, by instantaneous venesection; fainting fits, by cool air, application of cold water, and the use of volatiles; anasarca depending on pregnancy, by the lancet, and aperients, with mild diuretics. To enter more into the detail of the different diseases of pregnancy, would swell this article beyond reasonable bounds; nor, is it necessary, as the general principles of treatment have been freely and without reserve laid down. It will not, however, be proper to conclude this part, without adverting to a mechanical disease, which sometimes takes place between the third and fourth month of pregnancy, and which is known under the name of retroversion of the womb. It may at this period be produced by improper retention of the urine, by which the bladder is distended, the lower part of the uterus raised and brought forward, whilst the upper part is turned back, and thrown down between the vagina and rectum But it is quite a mistake to suppose that retention of urine is the sole cause, or, in many instances, more than a secondary one, of increasing that displacement which had begun to exist. From a careful examination of the progress and symptoms of this disorder, the writer is convinced that frequently it arises from an undue degree of prolapsus. The os uteri is brought lower and more forward than it ought to be, and the fundus lies back in the hollow of the sacrum. The uterus enlarges in this situation, and the fundus sinks lower, whilst the os uteri projects more forward, and obstructs the urine. The bladder becomes distended, and the retroversion is completed or increased thereby, if it had already taken place, by the mere subsidence of the fundus and consequent elevation of the opposite end, the uterus turning to a greater or less extent, like a beam of a balance on its axis. A moderate degree of malposition produces inconvenience, chiefly from the pressure it occasions on the orifice of the bladder, by which the urine cannot be evacuated. This not only occasions the usual painful sensations which accompany retention of urine, but very soon excites severe bearing-down pains, like those of labour. Partly from the effect produced on the lower part of the uterus by the distended bladder, but chiefly by the pressure of the superincumbent viscera, occasioned by the contraction of the abdominal muscles, the fundus is pressed lower, and the retroversion rendered more complete, and the bladder is still more closed up. The two prominent symptoms then of this complaint are, retention of urine, and bearing-down pains. These pains are more dependent on the state of the bladder than on the position of the uterus, for they are always worst when the bladder is fullest, or most irritated. Last of all, if the complaint be neglected, and the bladder continues unrelieved, inflammation takes place, and generally proves fatal. Our first and great object, therefore, ought to be, immediately to relieve the bladder, by introducing the catheter; and a regular recourse to this, keeping the bowels open, and allaying irritation, if necessary, by opiates, seldom fails in curing the patient. The best catheter to be employed is the gum one, and advantage may sometimes be derived from allowing it to remain in the bladder, so as to keep it constantly empty for some time. We have been urged to replace the uterus by pressure, but this often is not to be accomplished without much force, and in some cases, is almost impracticable. No instance has occurred to the writer where bad consequences followed from neglecting this attempt, and therefore he is still inclined to advise the more lenient though slower mode of trusting to the use of the catheter, rather than using force in endeavouring to replace the womb. At the same time, he has no objection, after the urine is drawn off, to make gentle pressure upwards on the fundus uterus, with the hand introduced into the vagina; but no strong efforts to elevate are advisable, nor, in any case, ought the attempt to be made, till the bladder be completely emptied.

CHAP. IV.

Of Abortion and Hemorrhage.

When the child is expelled so prematurely as to be unfit for living, the mother is said to suffer an abortion. This is always accompanied with separation of the ovum, and contraction of the womb itself. The first is production of discharge of blood, the second of pains analogous to those of labour. Sometimes the separation, and, in other cases, the contraction, is the first indication of abortion. If this event arise from any exertion, fright, or any other cause operating on the vessels, and occasioning detachment, the symptoms come on unexpectedly, and in general, the first is hemorrhage. If, however, it proceed from more latent causes, influencing the vitality of the fœtus itself, we usually observe certain precursory signs, which shew that the embryo or child is no longer alive. The morning sickness ceases, the breasts become flatter or fall off in size, the abdomen feels slack, and a sensation of heaviness is perceived in the lower part of it. If the patient be past the time of quickening, she now feels motion no more. Any one of these signs is not to be considered as evidence that abortion is inevitable, but when they are conjoined, there can be no doubt.

If the ovum be very inconsiderable in size, the symptoms attendant on abortion are chiefly those of uterine irritation, accompanied with hemorrhage, and differ little from those of painful menorrhagia. Nothing but coagula can be detected.

If the ovum be distinct, as in the second month, we have an attempt to contract, pains more or less regular, and greater disturbance of the abdominal viscera, and not unfrequently a tendency to syncope.

When the organization is more complete, and the ovum larger, as in the third month, we have still more distinct and regular pains, accompanied with hemorrhage and sympathetic symptoms. Sometimes the water is first discharged, then the fœtus, and last of all, the secundines; in other cases, the membranous bag comes away entire, enclosing the fœtus, and bringing along with it the fœtal posture of the placenta, and part of the decidua; the rest is afterwards thrown off.

When farther advanced, the process resembles still more nearly labour, except in being accompanied with greater discharge.

When the fœtus is expelled in abortion, it is usual for the discharge to mitigate, or stop for a time, then it returns, and sometimes with redoubled violence, previous to the expulsion of the secundines. These are thrown off, at different periods, from an hour to some days, but the general time is within 12 hours.

The duration of the whole process, as well as the nature and extent of the accompanying and sympathetic effects, vary much in different cases, and in some a portion, or the whole of the secundines, is so long retained as to become putrid, and produce bad consequences. In general, abortion is not attended with danger, if the constitution be not previously ruined, or the patient much sunk; but repeated miscarriages ultimately impair the health, and predispose to other diseases. Nor is the process itself altogether void of danger. Very lately, the author was consulted respecting a lady who had suffered a miscarriage in the second month, and who, when he saw her, was just expiring from hemorrhage, although she had been carefully and zealously attended by two intelligent gentlemen from the first.

A predisposition may be given to abortion by that imperfection which takes place in the uterus in advanced life. Repeated miscarriages also not only occasion a debility in the womb, but also, by the power of habit, give a tendency to injurious changes and actions about the same time in future pregnancies. General or local debility, produced in any way, has also a predisposing effect, and this is particularly the case when there is a relative plethora, or greater quantity of blood circulating in the vessels than their debilitated condition can sustain. An absolute plethora is another frequent predisposing cause, and is generally combined with an hemorrhagic disposition. Excessive irritability of the uterine system, or of the body altogether, renders abortion very apt to occur, and the same holds true of undue sympathy between the uterus and other organs. Some conditions of the ovum itself, too obscure to be detected, or which, either from the minuteness of the part, or destruction of organization which takes place, cannot be observed, must also be included. Delicacy of the membranes, excessive quantity of liquor amnii, diseased cord, or placenta, are amongst the number of causes. The exciting causes are numerous, and vary in different individuals. One of the most certain is, the death of the child, arising from affections or changes peculiar to itself, or from disorders and affections of the mother, such as sudden and severe cramp in the stomach or bowels. Passions of the mind have much influence on the uterus, disordering the circulation, and causing rupture of the connecting vessels, or exciting the muscular action of the womb. Violent sensations, as sudden immersion in cold water, or a large draught of cold drink, may cause abortion. Acrid medicine, or strong purgatives, or the irritation of piles, &c. are likewise exciting causes. Violent or sudden exertion, or any effort beyond the safe degree, will cause abortion; and in those who are predisposed to it, the most trifling exciting causes are sufficient.

Our object, in order to prevent abortion in those who are not yet threatened with it, is to counteract, as far as we can, the supposed predisposing causes, and avoid with care those which are existing. As a very frequent cause is plethora, with or without delicacy of the vessels of the ovum, a prominent part of attention is, the sanguiferous system. We lessen plethora by light diet, restriction in the quantity of liquids, laxatives, blood-letting, and moderate gentle exercise, if that be practicable, on account of the local condition. Diminution of the quantity of sleep, and avoiding heated rooms, and too warm beds, are also proper. When there is a strong predisposition, every thing which can excite the action of the uterus, or the activity of the vessels, must be shunned. Hence, in some cases, it may be necessary to confine the patient for some weeks, or even months, to a recumbent posture. It is needless to add, that all stimulants must be abstained from in such cases. When the cold bath agrees with the patient, it is useful, by rendering all the functions more perfect, and lessening the risk of plethora.

In debilitated habits, if the cold bath do not produce chilliness or disagreeable effects, it is of great utility. The diet ought to be neither so sparing as to continue, far less increase, weakness; nor, on the other hand, so full as to produce relative plethora.

Extreme irritability is lessened by laxatives, the shower bath, and, if combined with debility, by the use of light infusion of bark. If connected with plethora, as it often is, venesection is the best remedy. The repeated application of leeches to the neighbourhood of the vagina is a favourite remedy with some continental practitioners. In very nervous habits, when there is uneasiness in the uterine region, supposed to indicate the existence of spasm, the tepid bath, with antispasmodics, has been sometimes of service, and is certainly by no means dangerous.

When abortion is threatened, if we be not assured that the child is dead, we ought instantly to use means for stopping it. Blood-letting is a very general remedy, and a useful one, but it must not be carried too far; and the practitioner ought to regulate his conduct by scientific principles. There are chiefly two objects in employing the lancet; to lessen the activity of the circulation, and thereby diminish or check hemorrhage, and stop the farther separation of the ovum; and to abate irritability.

Spare diet, strict rest, cool air, tranquillity of mind. and the other means of lessening predisposition, must be rigidly enforced. The application of cold water to the back and perineum, by means of cloths, is often highly useful; and if the discharge be considerable, it ought to be commanded by stuffing the vagina. If there be any pain or general uneasiness, an opiate is useful; and, indeed, if there be no idiosyncrasy forbidding it, we ought in general to prescribe it. When there is a continued but moderate discharge, or repeated discharges, the use of a styptic injection is proper.

When we cannot prevent abortion from taking place, our next object is to conduct the process to a safe termination. The principal danger arises from the loss of blood, and therefore our chief attention ought to be paid to the prevention of this by stuffing, and the judicious use of cold. Faintness, feeling of sinking, or actual syncope, are removed by cool air, smelling hartshorn, opiates, and gentle cordials. The placenta ought, in general, to be left to come away by the uterine efforts; but, in the mean time, we must guard against hemorrhage by stuffing, or if the discharge be considerable, and the secundines can be brought away by the finger without irritation, that ought to be done.

When a portion of the placenta remains and putrefies, a febrile or hectic state is excited, the patient becomes sick, and the strength is much reduced both by fever and repeated hemorrhages, during the intervals of which fœtid matter is discharged from the vagina. The lower part of the belly is tumid, perhaps tender, and languor alternates with hysterical symptoms. If we can feel the portion, and easily extract it, this ought to be done; but we must not irritate. Injections of solutions of sulphate of alumine are proper, or of strong decoction of oak bark. The bowels are to be kept regular, the diet should be light aad nourishing; and the free use of fruit or vegetable acid, with the occasional exhibition of opiates, are proper. In prolonged cases, a gentle emetic may be of service in procuring the removal of the putrid mass.

It will be proper, in this place, to notice those hemorrhages which occur in the latter months of pregnancy, and which are attended with the greatest danger both to the mother and child. These have been divided into two classes; those arising from the implantation of the placenta over the os uteri, and those in which the placenta is attached higher up. This division is highly proper in one respect, but is neither safe nor useful, if it is to give rise to a rule of practice peculiar to each kind. The only safe rule is a general one, that no patient, in flooding, can be with impunity allowed to remain undelivered, after the state of the os uteri will permit of delivery.

The first attack of hemorrhage is in general sudden and severe, but it soon is suspended, or at least moderated. It often takes place during the night, and is usually unattended with pain. The effects produced by the first attack will depend on the strength and habit of the patient, and the severity of the hemorrhage. By a recurrence of the discharge, the strength however in every instance is greatly reduced, the patient becomes pale, and the pulse feeble. At the same time, slight but inefficient pains are excited. The os uteri becomes soft and dilatable, perhaps partially dilated, and hopes are entertained that labour shall come on and safely relieve the patient. Such hopes are never entertained by any man who understands the nature of the case, for although one or two patients may thus escape out of many hundreds, the rest die undelivered.

The plain and obvious practice to be followed is, to restrain the discharge by stuffing the vagina until the os uteri becomes dilatable, and then deliver the patient by turning the child. We thus do not interfere so early as to produce injurious irritation by harshly opening the os uteri, nor do we, on the other hand, permit the strength to be sunk to a hazardous degree. The concomitant treatment must proceed on general principles.

Part II. OF PARTURITION.

CHAP. I.

Of the Classification of Labours.

Labour may be defined to be the expulsive efforts made by the uterus for the birth of the child, after it has acquired such a degree of maturity as to give it a chance of living independently of its uterine appendages.

Labours may be divided into seven classes.

Class I. Natural labour; which may be defined to be labour taking place at the end of the ninth month of pregnancy; the child presenting the central portion of the sagittal suture, and the forehead being directed at first toward the sacro-iliac symphysis; a due proportion existing between the size of the head and the capacity of the pelvis; the pains being regular and effective; the process not continuing beyond 24 hours, seldom above 12, and very often not for six; no morbid affection supervening capable of preventing delivery, or endangering the life of the woman.

This comprehends only one order.

Class II. Premature labour; or labour taking place considerably before the completion of the usual period of utero-gestation, but yet not so early as necessarily to prevent the child from surviving.

This comprehends only one order.

Class III. Preternatural labours; or those in which the presentation or position of the child, is different from that which occurs in natural labour, or in which the uterus contains a plurality of children, or monsters.

This comprehends seven orders.

Order 1. Presentation of the breech.

Order 2. Presentation of the inferior extremities.

Order 3. Presentation of the superior extremities.

Order 4. Presentation of the back, belly, or sides of the child.

Order 5. Mal-position of the head.

Order 6 Presentation of the funis.

Order 7. Plurality of children, or monsters.

Class IV Tedious labour, or labour protracted beyond the usual duration; the delay not caused by the mal-position of the child, and the process capable of being finished safely, without the use of extracting instruments.

This comprehends two orders.

Order 1. Where the delay proceeds from some imperfection or irregularity of muscular action.

Order 2. Where it is dependent principally on some mechanical impediment.

Class V. Laborious or instrumental labour; labour which cannot be completed without the use of extracting instruments, or altering the próportion betwixt the size of the child and the capacity of the pelvis.

This comprehends two orders.

Order 1. The case admitting the use of such instruments as do not necessarily destroy the child.

Order 2. The obstacle to delivery being so great, as to require that the life of the child should be sacrificed for the safety of the mother.

Class VI. Impracticable labour; labour in which the child, even when reduced in size, cannot pass through the pelvis.

This comprehends only one order.

Class VII. Complicated labour; labour attended with some dangerous or troublesome accident or disease, connected in particular instances with the process of parturition.

This comprehends six orders.

Order 1. Labour complicated with uterine hemorrhage.

Order 2 Labour complicated with hemorrhage from other organs.

Order. 3. Labour complicated with syncope.

Order 4. Labour complicated with convulsions.

Order 5. Labour complicated with rupture of the uterus.

Order 6. Labour complicated with suppression of urine, or rupture of the bladder.*

---

* The classification of labours is arbitrary, and varies according to the views of the writers and teachers of midwifery. Baudelocque, the most experienced of the French practitioners, and an able writer, has the following division:

1st. Labours which are accomplished by the efforts of nature alone.

2nd. Labours which require the assistance of art, but which may be completed by the aid of the hand alone.

CHAP. II.

Of Natural Labour.

The intention of labour is to expel the child and secundines. For this purpose, the first thing to be done by the process, is to dilate, to a sufficient degree, the os uteri, so that the child may pass through it. The next point to be gained is, the expulsion of the child itself, and last of all the fœtal appendages are to be thrown off. The process may therefore be divided into three stages. The first stage is generally the most tedious. It is attended with frequent but usually short pains, which are described as being sharp, and sometimes so severe as to be called cutting or grinding. They commonly begin in the back, and extend toward the pubis or top of the thighs; but there is in this respect a great diversity with different women, or the same woman at different times. Sometimes the pain is felt chiefly or entirely in the abdomen, the back being not at all affected during this stage; and it is generally observed, that such pains are not so effective as those which affect the back. Or the pain produced by the contraction of the womb may be felt in the uterine region; and when it goes off, may be succeeded by a distressing aching in the back. In these cases, the pain is confined to the small of the back and upper part of the sacrum, and is either of a dull aching kind, or sharp and acute, and, in some instances, is attended with a considerable degree of sickness, or tendency to syncope. The most regular manner of attack, is for pains to be at first confined to the back, descending lower by degrees, and extending round to the belly, pubis, or top and fore part of the thighs, and gradually stretching down the back part of the thighs, the fore part becoming easy: occasionally one thigh alone is affected. At this time, also, one of the legs is sometimes affected with cramp. The duration of each pain is variable. At first it is very short, not lasting above half a minute, perhaps not so long; but by degrees it remains longer, and become more severe. The aggravation, however, is not uniform; for sometimes, in the middle of the stage, the pains are shorter and more trifling than in the former part of it. During the intermission of the pains the woman is sometimes very drowsy, but at other times is particularly irritable and watchful. The pains are early attended with a desire to grasp or hold by the nearest object, and at the same time the cheeks become flushed, and the colour increases with the severity of the pain. The os uteri being considerably dilated, the second stage begins. The pains become different, they are felt lower down, they are more protracted, and attended with a sense of bearing down, or an involuntary desire to expel or strain with the muscles; and this desire is very often accompanied with a strong inclination to go to stool. A perspiration breaks out, and the pulse, which, during the first stage, beat rather more frequently that usual, becomes still quicker, the woman complains of being hot, and generally the mouth is parched. Soon after the commencement of this stage, it is usual for the liquor amnii to be discharged. This is often followed by a short respite from pain; but presently the efforts are redoubled. Sometimes there is no cessation, but the pains immediately become more severe, and sensibly effective. The perineum now begins to be pressed outward, and the labia are put upon the stretch. The protrusion of the perineum gradually increases, but it is not constant; for when the pain goes off, the head generally recedes a little, and the perineum is relaxed. Presently the head descends so low, that the parts are kept permanently on the stretch, and the anus is carried forward. Then the vertex pressing forward, the labia are elongated, and the orifice of the vagina dilated. The perineum is very thin, much stretched, and spread over the head of the child. As the head passes out, the perineum goes back over the forehead, becoming narrower, but still more distended laterally. If the perineum did not move backward as the head moved forward, it would run a greater risk of being torn; and indeed, even in the most regularly conducted labour, a part of it is often rent. Delivery of the head is accomplished with very severe suffering; but immediately afterwards the woman feels easy, and free from pain. In a very little time, however, the uterus again acts, and the rest of the child is expelled, which completes the second stage of labour. The expulsion of the body is generally accomplished very easily and quickly; but sometimes the woman suffers several strong and forcing pains before the shoulders are expelled. The birth of the child is succeeded, after a short calm, by a very slight degree of pain, which is consequent to that contraction which is necessary for the expulsion of the placenta. This expulsion is accompanied and preceded by a slight discharge of blood, which is continued, but in decreasing quantity, for a few days, under the name of the red lochia.

The existence and progress of labour, and the manner in which the child is placed, are ascertained by examination *per vaginam*.

Before labour begins, the os uteri is generally closed, and directed backwards towards the sacrum. When we examine, in the commencement of labour, the os uteri is to be sought for near the sacrum, at the back part of the pelvis, whilst between that spot and the pubis we can pass the finger along the fore part of the cervix uteri. On this the presenting part of the child

---

3rd Labours which cannot be accomplished without the aid of instruments; or in which it is useful to employ them.

The classification adopted in the lectures on Midwifery in the University of Pennsylvania, is that of Smellie, improved by Hamilton and Denman, viz.

1st. Natural labour, where the head presents, and the child is expelled by the natural pains.

2nd. Difficult labour, where the head presents, but the birth is uncommonly protracted, or requires the interposition of art.

3rd. Preternatural labour, when any other part than the head first presents.

4th. Anomalous or complex labours, including those attended with hæmorrhage; with convulsions; when there is a plurality of children; or where the funis umbilicalis presents before the child—to which may be added, labours attended with rupture, or inversion of the uterus.

Each of the three first classes admit of divisions into *Orders*, which it is unnecessary to enumerate here.

J.

rests, so that in natural labour it assumes somewhat the shape of the head; and, for the sake of distinction, we shall call it the tumour.

In some, it is so firmly applied to the head, and so tense, that a superficaical observer would take it for the head itself. In this case the labour often is lingering. This tumour, or portion of the uterus, is broad in the beginning of labour, but becomes narrower as the os uteri dilates, until at last it is completely effaced, the head either naked, or covered by the membranes occupying the vagina. The breadth of this portion of the uterus, therefore, as well as the examination of the os uteri, will serve to ascertain the state of the labour. The protrusion of the membranes, and discharge of the liquor amnii, ought to bear a certain relation to the advancement of labour. Whilst the os uteri is beginning to dilate, the membranes have little tension; they scarcely protrude through the os uteri, until it be considerably opened. But in proportion as the dilatation advances, and the pains become of the pressing kind, the membranes are rendered more tense, protruding during a pain, and becoming slack and receding when it goes off. In the first stage of labour, the head will be found placed obliquely along the upper part of the pelvis, with the vertex directed toward one of the acetabula. The finger can easily ascertain the sagittal, and afterwards the lamboidal suture; the central portion of the sagittal suture is the point from which we set out, and, if the finger be readily led to the angle formed by the posterior edges of the parietal bones, we may be sure that the presentation is favourable. If, on the other hand, we can feel the anterior fontanelle, the vertex is generally directed to the sacro-iliac articulation. When the pelvis is well formed, and the cranium of due size, the head may commonly be felt in every stage of labour; but there are cases in which, even although the pelvis be ample, it is not easily touched for some time.

When the vertex comes to present at the orifice of the vagina, or passes a line drawn from the under edge of the symphysis pubis back to the sacrum, the perineum and skin near the tuberosities of the ischia become full, as if swelled, but not tense. This at first proceeds from relaxation of the muscles, and some degree of descent of the vagina and rectum. Whenever this is felt, we may be sure that the head is descending; but although a few pains may distend the perineum, it may yet be some hours before this takes place, the pains for all that time appearing to produce very little effect, although the pelvis be well formed. Should the perineum become stretched, and the anus be carried forward a little during the pain, we may expect that delivery is at hand. If the patient have already born children, the child is sometimes delivered within a few minutes after the perineum is first felt to become full.

It is immaterial in what posture the patient place herself during the first stage of labour; but in the second stage, when delivery is approaching, it is proper that she be placed on her side, and it is usual for her to lie on her left side, as this enables the practitioner to use his right hand. The knees are a little drawn up, and generally at this time kept separate by means of a small pillow placed between them. Many women wish to have their feet supported, or pressed against by an assistant, and it is customary to give her a towel to grasp in her hand. This is either held by the nurse, or fastened to the bed-post. We must however be careful that these contrivances do not encourage the woman to make too strong efforts to bear down. When the patient is in bed, it is proper to have a soft warm cloth applied to the external parts, in order to absorb any mucus or water that may be discharged—and this is to be removed when it is wet. Attempts to dilate the os uteri or the vagina in natural labour, and the application of unctuous substances to lubricate the parts, are now very properly abandoned by well-instructed practitioners. The membranes ought generally to be allowed to burst by the efforts of the uterus alone, for this is the regular course of nature, and a premature evacuation of the water either disorders the process and retards the labour, or, if it accelerate the labour, it renders it more painful. We cannot, however, go the length of some, who say, that the artificial evacuation of the water is always hurtful; for there are circumstances in which it may be allowable and beneficial.

Examination ought, in the first stage of labour, to be practised seldom; but, in the second stage, we must have recourse to it more frequently; and when the pains are becoming stronger, and the head advancing, we must not leave the bedside.

As the fæces are generally passed at this time involuntarily, a soft cloth is to be laid on the perineum; and when the second stage of labour is drawing to a conclusion, the hand is to be placed on this, in order to prevent the rapid delivery of the head, and the consequent laceration of the perineum. This is a point of very great importance, and which requires to be carefully considered by the practitioner.

The last advice to be given respecting this stage of labour is, that as we retard rather than encourage the expulsion of the head, so we are not to accelerate the delivery of the body.

The child being born, a ligature is to be applied on the cord very near the navel, and another about two inches nearer the placenta. It is then to be divided betwixt them, and the child removed. The hand is next to be placed on the belly, to ascertain that there be not a second child, and the finger may, for the same purpose, be slid gently along the cord to the os uteri. The hand of an assistant should be applied on the abdomen, and gently pressed on the uterus, which may excite it to action, and prevent torpor. If the placenta be not expelled soon, the uterine region may be rubbed with the hand, to excite the contraction of the womb. Immediately after the expulsion of the child there is often a copious evacuation of water, which is sometimes mistaken by the woman for a discharge of blood. But hemorrhage never takes place so instantaneously, in such quantity. It is generally a minute or two, sometimes much longer, before flooding comes on. Against the occurrence of this, we are to be on our guard.

Soon after the birth of the child, the placenta is expelled, and this process is accompanied by a trifling discharge of blood and a little pain. However, it sometimes happens that it is retained, and the retention may or may not be complicated with flooding. If it be, all are agreed on the propriety of introducing the hand first to excite the uterus, and then to extract the placenta. But if their be no flooding, many, from a fanciful conceit of the powers of nature, are for doing nothing. It is warrantable and proper to extract it entirely at the end of an hour, if it be still retained.

In every instance, but more particularly of tedious labour, and in those cases where there has been the smallest indication of irregular or spasmodic action of the womb, it is indispensable that we repeatedly ascertain that no hemorrhage has taken place; and this ought not to be neglected, even after the placenta has been naturally expelled. Whether the placenta be retained or thrown off, the treatment is the same, namely, to excite the regular contraction of the uterine fibres. This is without loss of time to be done, by introducing the hand into the uterus, when, in almost every instance, it will be found that a circular or spasmodic contraction has taken place. This is to be gently dilated with the hand, which is to be moved constantly or pressed lightly against the interior surface, so as to excite universal action; nor is it to be withdrawn till that be accomplished. If the placenta be still retained, it is to be carefully brought down through the contraction into the inferior part of the womb, when it may be left so long as the spasm remains. Pressing on the abdomen, particularly over the uterus, and gently grasping of the womb, through the abdominal position, tends to excite action, whilst the exhibition of a full dose of laudanum contributes to allay the spasm. The strength is in the mean time to be supported by stimulants; and when the attack has been severe, by the sedulous use of light nourishment. We must not, however, carry the cordial plan too far, as there is in such cases a propensity to inflammation of the womb afterwards.

CHAP. III.

Of Premature Labour.

When labour is established, it is to be conducted much in the same way with parturition at the full time; but the following observations will not be improper. The patient must avoid much motion, lest hemorrhage be excited. Frequent examination and every irritation are hurtful, by retarding the process, and tending to produce spasmodic contraction. If this contraction take place, marked by paroxyms of pain, referred to the belly or pubis, little or no effect being produced on the os uteri, a full dose of tincture of opium should be given, after the administration of a clyster. Severe pains, with premature efforts to bear down and a rigid state of the os uteri, require venesection, and afterwards an opiate. The delivery of the child is to be retarded rather than accelerated in the last stage, that the uterus may contract on the placenta. This is farther assisted by rubbing gently the uterine region after delivery. If the placenta be long retained, or hemorrhage come on, the hand is to be gently introduced into the uterus, and pressed on the placenta to excite the fibres to throw it off. We should not rashly attempt to remove it, for we are apt to tear it; neither are we to pull the cord, for it is easily broken. In those cases where premature labour is connected with redundance of liquor amnii, it is useful to introduce the hand immediately on the delivery of the child, for the placenta is apt to be retained by irregular contraction. We do not instantly extract the placenta, but it is desirable to get the hand in contact with it before the circular fibres contract. Great attention is to be paid to the patient for some days after delivery, as she is liable to a febrile affection, which may be either of the inflammatory type, or of the nature of weed, to be afterwards noticed.

CHAP. IV.

Of Preternatural Labour.

Order First.

The breech is distinguished by its size and fleshy feel, by the tuberocity of the ischia, the shape of the ilium, the sulcus between the thighs, the parts of generation, and by the discharge of meconium, which very often takes place in the progress of labour. After the breech has descended some way into the pelvis, the integuments may become tense or swelled, so as to make it resemble the head. Before the membranes burst, the presentation is usually very mobile, and bounds up readily from the finger, but in some instances it is from the first firmly pressed down in the pelvis, and felt through the uterus very much resembling the head.

Many have advised, that when the breech presented, the feet should be brought down first; but the established practice now is, when the pelvis is well formed, and other circumstances require speedy delivery, to allow the breech to be expelled without any interference, until it has passed the external parts.

Order Second.

Presentation of the feet is known, by there being no rounded tumour formed by the lower part of the uterus. The membranes also protrude in a more elongated form than when the head or breech present. The presenting part, when touched during the remission of the pain, is found to be small, and affords no resistance to the finger. When the membranes break, we may discover the shape of the toes and heel, and the articulation at the ankle. Sometimes both the feet and the breech present. Two circumstances contribute to an easy delivery; *first*, That the toes be turned to the sacro-iliac junction of the mother; and *secondly*, That both feet come down together. The best practice is, to avoid rupturing the membranes till the os uteri be sufficiently dilated; then we grasp both feet and bring them into the vagina; or, if both present together at the os uteri, we may allow them to come down unassisted.

Order Third.

When the shoulder or arm presents, the case has the general character of preternatural presentations. The round tumour, formed by the head in natural labour, is absent, whilst we can ascertain the shape and connection of the arm and shoulder. A shoulder presentation can only be confounded with that of the breech. But, in the former case, the shape of the scapula, the ribs, the sharpness of the shoulder-joint, and the direction of the humerus, together with our often feeling in our examination either the hand or neck, will be distinguishing marks. In the latter, the rounder shape and greater firmness of the ischium, the size of the thigh, its direction upwards, and its lying in contact with the soft belly, the spine of the ilium, the parts of generation, the size of the tuberosity of the ischium, and the general shape of the back parts of the pelvis, contribute with certainty to ascertain the nature of the case.

In most cases where the superior extremities present, the feet of the child are found in the fore part of the uterus, toward the navel of the mother. But their situation may be known by examining the presentation.

We should be careful not to rupture the membranes prematurely; and more effectually to preserve them entire, we must prevent exertion, or much motion on the part of the mother. As soon as the os uteri is soft, and easily dilatable, the hand should be introduced slowly into the vagina, the os uteri gently dilated, and the membranes ruptured. The hand is then immediately to be carried into the uterus, and upwards till the feet are found. Both feet are to be grasped betwixt our fingers, and brought down into the vagina, taking care that the toes are turned to the back of the mother. The remaining steps have been already described.

But if the water have been long evacuated, then the fibres of the uterus contract strongly on the child, the presentation is forced firmly down, and the whole body is compressed so much, that the circulation in the cord is frequently impeded, and, if the labour be protracted, the child may be killed. This is a very troublesome case, and requires great caution. If the pains be frequent, and the contraction strong, then all attempts to introduce the hand, and turn the child, must not only produce great agony, but, if obstinately persisted in, may tear the uterus from the vagina, or lacerate its cervix or body. Copious blood-letting certainly has a power in many cases of rendering turning easy. If the patient be restless and feverish, or the part rigid, it is to a certain extent necessary and proper, and ought to precede an opiate; but if these states do not exist, we shall generally succeed, by at once giving a powerful dose of tincture of opium, not less than sixty or eighty drops. Previous to this, the bladder is to be emptied, lest it should be ruptured during the operation; and, if necessary, a clyster is to be administered. The patient is then to be left, if possible, at rest. Sometimes in half an hour, but almost always within two hours after the anodyne has been taken, the pains become so far suspended, as to render the operation safe, and perhaps easy.

In some instances, when no attempt was made to turn the child, the uterus has burst, and the patient died, whilst, in others, nature has at length effected the expulsion with safety to the mother.

A knowledge of the fact that the child may be thus evolved does not exonerate us from making attempts to turn; for although a considerable number of cases are recorded where it has taken place, yet these are few in proportion to the number of presentations of the shoulder; and in a large city containing above 100,000 inhabitants, the author has only learned of one instance where this has taken place.

Order Fourth.

The hips, back, belly, breast, or sides, may, though very rarely, present, the child lying more or less transversely. The hip is sometimes taken for the head, but is to be distinguished by the shape and relations of the ilium. In all the other cases, the presentation remains long high; but when the finger can reach it, the precise part may be ascertained, by one who is accustomed to feel the body of a child. In these presentations the hand should be introduced, to find the feet, by which the child is to be delivered. This rule is absolute with regard to all those presentations, except that of the hip, which only renders labour tedious, and in this the practice must be determined by concomitant circumstances.

Order Fifth.

The child may present the head, and yet it may be improperly situated, and give rise to painful and tedious labour.

1st, The forehead, instead of the vertex, may be turned towards the acetabulum. In this case, the presentation is felt in the first stage high up, smooth, and flatter than usual. In a little longer, we discover the anterior fontanelle, and the situation of the sutures. By degrees, the head enters the cavity of the pelvis, the vertex being turned into the hollow of the sacrum, and by a continuance of the pains, the forehead either turns up within the pubis, and the vertex passes out over the perineum, or the face gradually descends, and the chin clears the arch of the pubis, the vertex turning up within the perineum towards the sacrum, till the face is born. The first is the usual process in this presentation; all the steps of the labour are tedious, and often, for a considerable period, the pains seem to produce no effect whatever. In the last stage, the perineum is considerably distended, and it requires care and patience to prevent laceration. If it be discovered early, it is certainly proper to rupture the membranes, and turn the vertex round; a proceeding which is easily accompl shed, and which prevents much pain and fretfulness. If this opportunity be lost, we may still give assistance. The late Dr. Clarke says, that in thirteen out of fourteen cases, he succeeded in turning round the vertex, by introducing either one or two fingers between the side of the head near the coronal suture and the symphysis of the pubis, and pressing steadily, during a pain, against the parietal bone.* The writer of this article fully concurs in the opinion given by that excellent practitioner. The fontanelle, or crown of the head, may also present, although the face be turned to the sacro-iliac junction. In this case it is felt early, and, by tracing the coronal suture, we may ascertain whether the frontal bones lie before or behind. It is a much more uncommon presentation than that noticed above. The labour is, at first, a little slower than in a natural presentation, but, by degrees, the head becomes more oblique, the vertex descending; and this may be assisted, by supporting the forehead with the finger during a pain.

2d, The side of the head may present. In this case the presentation is long of being felt, but it is recognised by the ear. If, however, it has been long pressed in the pelvis, it is extremely difficult to determine the case. It is very rare, and has even been deemed to be impossible. In some instances the child has been

---

* This mode of proceeding appears to have been first recommended by Baudelocque. J.

turned, but it is most common to rectify the position of the head, by introducing the hand.

3*d*, The occiput may present, the triangular part of the bone being felt at the os uteri. It is known by its shape, by the lamboidal suture, and its vicinity to the neck. The forehead rests on some part of one of the psoæ-muscles, and from this oblique position of the head, the labour is tedious. It has been proposed, in this case, to turn; but it is better, if we do any thing, to rectify the position of the head with the hand. Nature is, however, adequate to the delivery, even if not assisted.

4*th*, The face may present, with the chin to one of the acetabula, or to the sacro-iliac junction, or to the pubis or sacrum. The first two are the best, the third is more troublesome, and the last is worst of all.

If the presentation be discovered early, there can be little doubt as to the propriety of rectifying the position, but, if the labour be advanced, this is difficult; and then it only remains that we should endeavour, if the labour be severe and tedious, to make the face descend obliquely, by cautiously, but firmly supporting with a finger, during the pains, the chin or end which is highest, in order to favour the descent of the lower end. When the chin has advanced so far as to come near the arch of the pubis, we may follow a different method, and gently depress it, which assists the delivery, for generally the chin is first evolved.

Order Sixth.

Sometimes the cord descends before, or along with the presenting part of the child. This has no influence on the process of delivery, but it may have a fatal effect on the child. As soon as the os uteri will admit the introduction of the hand, the child should be turned, if it can be easily done. But if the presentation be advanced before we are called, and turning be difficult, then we must endeavour to keep the cord slack, or remove it to that part of the pelvis where it is least liable to be compressed: or it will be still better to endeavour, with two fingers, to push the cord slowly past the head, and prevent it, for two or three pains, from coming down again.*

Should this not be practicable, and the pulsation suffer, or the circulation be endangered, we must accelerate labour by the forceps.

Order Seventh.

The signs by which the existence of a plurality of children are said to be indicated, are so completely fallacious, that no reliance can be placed upon them, nor can we generally determine the existence of twins, until the first child be born. Then, by placing the hand on the abdomen, the uterus is felt large, if it contain another child, and by examination *per vaginam*, the second set of membranes, or some part of the child, is found to present. This mode of inquiry is proper after every delivery.

If the first child present the head, the second generally presents the breech or feet, and *vice versa;* but sometimes the first presents the arm, and, in that case, when we turn, we must be careful that the feet of the same child be brought down. This first being delivered, the hand is to be again introduced, to search for the feet of the second child, which are to be brought into the vagina, but the delivery is not to be hurried.

It sometimes happens that, after the first child is born, the pains become suspended, and the second is not born for several hours. Now this is an unpleasant state, both for the patient and practitioner. She must discover that there is something unusual about her; he must be conscious that hemorrhage, or some other dangerous symptom, may supervene. The first rule to be observed is, that the accoucheur is on no account to leave his patient till she be delivered. The second regards the time for delivering. Some have advised that the case be entirely left to the efforts of nature, whilst others recommend a speedy delivery. The safest practice, if the head present, lies between the two opinions. If effective pains do not come on in an hour, the child ought to be delivered by turning.

It remains to be observed, that we ought to be peculiarly careful in conducting the expulsion of the placentæ of twins. Owing to the distention of the uterus, and its continued action in expelling two children, there is a greater than usual risk of uterine hemorrhage taking place. The patient must be kept very quiet and cool; gentle pressure should be made with the hand externally on the womb, and no forcible attempts are to be permitted for the extraction of the placentæ, by pulling the cords. If hemorrhage come on, then the hand is to be introduced to excite the uterine action, and the two placentæ are to be extracted together. The application of the bandage, and other subsequent arrangements, must be conducted with caution, lest hemorrhage be excited.

CHAP. V.

Of Tedious Labour.

Order First.

Tedious labour may occur under three different circumstances:

First, The pains may be from the beginning weak or few, and the labour may be long of becoming brisk.

Second, The pains during the first stage may be sharp and frequent, but not effective; in consequence of which the power of the uterus is worn out before the head of the child have fully entered into the pelvis, or come into a situation to be expelled.

Third, The pains during the whole course may be strong and brisk, but, from some mechanical obstacle, delivery may be long prevented, and it may even be necessary to have recourse to artificial force.

Different causes may produce tedious labour, which cannot be minutely enumerated in this place. Amongst these we may mention a slight disproportion between the capacity of the pelvis and the size of the head of the child, rigidity of the soft parts, unnatural strength of the membranes, &c. One of the most frequent is, inefficient action of the uterus, during which the pains, though productive, perhaps, of considerable sensation, have little efficacy, or they may be deficient both in point of sensation and effect. Various causes may pro-

* In these cases it is recommended to raise the hips of the patient considerably above the level of the head, and keep them in that situation until the cord may have receded, and the presenting part of the child taken its place. J.

duce this; as for instance, premature evacuation of the liquor amnii, undue distention of the womb, torpor of the uterine fibres, passions of the mind, &c. and it is a fact, that the same exciting causes may, in different cases, produce very different, and even opposite effects, in consequence of concomitant circumstances. In general, it is not necesssary to interfere artificially, unless the labour be unusually tedious, or complicated with some urgent symptoms. Stimulants are neither safe nor allowable, if we except the exhibition of a clyster, to excite the uterus sympathetically. An opposite plan is more useful, namely, instead of endeavouring to increase the force, to diminish the resistance, which is most readily done by venesection. Hippocrates was well acquainted with the good effect of detracting blood in facilitating labour. He advised it to be taken from the foot, but the modus operandi is the same, whatever vein be opened, and it is deeply to be regretted, that the opinion of this great man was so long neglected. Blood-letting is safe in every case, where a debilitated constitution, or exhausted system, or previous fatigue, do not forbid it. In many cases, more particularly when the os uteri is rigid, or the soft parts do not relax, it is productive of most speedy improvement. The diminution of resistance, and augmentation of expulsive force, do not bear an exact proportion to each other, but the latter is in a high ratio to the former, and when the expulsive action is once much excited, it goes on increasing. This principle is illustrated by the fact, that parturition is greatly accelerated by rupturing the membranes, and thereby allowing the water to run out, and the uterus to contract; a practice which ought not to be adopted unnecessarily, but which, in tedious labour, is often attended with most marked benefit. A change of posture also is useful, so as to make the power of gravity correspond with the uterine efforts. Hence, standing or kneeling is often of benefit; an erect position is also of service, by the stimulus given to the sensible os uteri by the greater pressure of the presentation. Walking gives an additional excitement to the action. Another advice to be given is highly important, namely, that when the pains are regular, but not effective, and the labour proves to be tedious, the os uteri should be gently dilated, so as to be completely opened within from ten to fourteen hours from the establishment of labour. The exact time cannot be laid down to suit any case, as a little latitude within these periods must be allowed, according to the state of the pains and the condition of the patient, and the effect already produced on the os uteri. It is not meant to say that the rule is absolute; for pains may, after continuing a few hours, go off for a day, and the os uteri may scarcely be affected. In such cases, interference is improper. But if the pains have regularly continued, and the os uteri have yielded slowly, and to an imperfect extent, and the presentation is felt resting on it, a delay beyond 12 hours will generally be productive of future exhaustion of the uterus. This is a principle which has most ably been explained by Dr. Hamilton, who has insisted on the great danger of allowing the first stage of labour to be unduly protracted. By pressing steadily but gently on the anterior margin of the os uteri during a pain, with two fingers resting on the head, it is safely and easily dilated to its full extent, by persisting for several pains in succession, or repeating our gentle endeavour at longer intervals. This, especially if preceded by blood-letting, never fails to dilate completely the os uteri; and those natural efforts of the womb, which would have otherwise been requisite to open the mouth of the womb, are spared, and the strength and force directed to the expulsion of the child. The pains generally become stronger and bearing down, not so much from the gentle stimulus applied to the os uteri, as on the principle already laid down. All resistance is taken away from the lower part of the uterine cavity, and the muscular action has only to force the head through the pelvis. Even when the necessity of instrumental aid is anticipated, this practice ought to be adopted; and indeed in such cases, above all others, is important. When the os uteri is rigid or tumid, blood-letting ought never to be omitted, unless the patient be debilitated, and at once render it dilatable and soft. In this desirable state of the mouth of the womb, if its aperture be equal to half-a-crown, the membranes may be ruptured with advantage, if they have not already given way; and the principle on which this advice is given has been explained above. On the other hand, when the os uteri is rigid, the membranes ought to be preserved entire until relaxation take place. Opening them is also improper, if the os uteri be very irritable. The writer is well aware that these directions may be misrepresented, and, perhaps, by some ignorant people misunderstood, and supposed to encourage rashness and irritation, and improper interference with natural labour. He is little accustomed to conceal his sentiments, from the wish to screen responsibility, and believing that these opinions are of great importance in the management of tedious labour, he deems it a duty to support and recommend them. When the pains are deficient from debility, excited by previous fatigue, it is generally proper to procure a suspension by an opiate, more especially if the water have been discharged. In a state of fatigue, when we wish to procure rest, or when the os uteri remains rigid, and in a debilitated patient, where we dare not use the lancet with safety, a full dose ought to be given, and it is most safely administered as a clyster. On the other hand, when our object is to excite the pains rather than to suspend them, a small dose, 20 or 25 drops for instance, may be given, and often has the effect of rendering the action brisker.* It is useful previously to learn, if we can, how the medicine agrees with the patient. The strength is to be supported by light and mild nourishment, and sometimes a little wine.

Irregular action of the uterine fibres is another cause of tedious labour, and which, amongst other sources, very often arises from the spontaneous discharge of the liquor amnii before, or in the commencement of labour. The pains produce little effect, and when they go off, leave behind them a distressing uneasiness in the back. A saline clyster, and pressing up the head of the child gently during a pain, to procure the more perfect evacuation of the liquor amnii, are useful. Blood-letting is proper, if the os uteri be rigid or tumid, which is often the case, especially if the waters have been prematurely discharged. If these means fail, or have not been proper, as for instance in consequence of previous debility, an ano-

* For the purpose of exciting more energetic contractions of the uterus in the cases alluded to above, nothing has been found so effectual as the ergot of rye, by some called Secale Cornutum, in doses of 15 or 20 grains, but not repeated frequently. J.

dyne clyster, or opium suppository, is of benefit. If this state should exist, without evacuation of the water, it is useful, if the os uteri be soft, thin, and considerably dilated, to rupture the membranes. In all these cases, the advice already given, not to allow the os uteri to remain too long undilated, ought to be acted on. After a time the child is expelled, but spasmodic contraction and hemorrhage are apt to follow. When labour is rendered tedious, by the accession of fever, or local inflammation, the lancet and cool air, with a laxative clyster, are the most useful means of relief, whilst timely recourse should be had to the forceps, if necessary.

Order Second.

When there exists a disproportion between the size of the child and the capacity of the pelvis, labour must be more or less tedious and severe. In such cases, our attention ought to be directed to the regulation of the bowels, evacuation of the urine, the preservation of strength, particularly by avoiding all unnecessary exertion, the procuring of sleep, and a respite from suffering, if that can be safely done by an opiate, and, above all, to the prevention of dangerous exhaustion, by not permitting the first stage of labour, or the complete dilatation of the os uteri to be too long protracted, and afterwards having timely recourse to artificial delivery.

CHAP. VI.

Of Instrumental Labour.

Order First.

When the head of the child, and the cavity of the pelvis, do not bear a just proportion to each other, the resistance to the passage of the head may be so great as to prevent the safe delivery of the child. The increased obstacle either for a time checks the full expulsive action of the womb, and ultimately unfits it for accomplishing its purpose, or affords such resistance as not to be safely overcome by the most severe efforts which are ultimately excited. It is, however, a great error to suppose, that this is the only case requiring the aid of instruments; for the resistance afforded by the soft parts, and various other causes influencing the action of the uterus, and producing tedious labour, may render them necessary. Many females require the forceps for the delivery of their first child, who afterwards are naturally delivered both with facility and celerity. These two cases have been noticed by practical writers under the distinction of impaction and arrest, the first being supposed, and justly, to require more prompt interference than the second. It is, however, much to be feared, that in both there is an undue backwardness to interfere, and an overweaning confidence placed in the powers of nature. It is indeed true, that, in many of these cases, the child may be at last expelled without artificial aid; but in no small proportion of instances there is good ground to fear that it shall be still-born, and that the mother shall sink from hemorrhage or exhaustion, or have fatal inflammation excited. The danger in protracted labour is greater to the child than the mother; that is, the one perishes sooner than the other. From the tables of Dr. Breen, exhibiting the result of the practice in the Dublin lying-in hospital, it appears that, out of 196 women who had tedious labour of their first child, but were delivered by the efforts of nature, 59 bore dead children; that is, three-tenths of the children were lost. If we come to particulars, we find, that when the labour lasted from 30 to 40 hours, rather more than one-fifth of the children was lost, and 1 woman in 34 died. When it lasted from 40 to 50 hours, three-tenths of the children were lost, and one woman in 13. When it continued from 50 to 60 hours, 1 woman in 11 died, and not quite one-third of the children were still-born. It is impossible to form a comparison of these results with those where instruments were employed, because they were always delayed long, or, when employed early, were resorted to under dangerous circumstances. In little more than half a century, 780,001 women were delivered in the Dublin hospital, and at an average 1 child in 18 was still-born. The deaths among women were as 1 to 92. It is impossible to draw all the important conclusions here which might be done from these documents; but the following facts cannot fail to strike the reader. In women who were between 30 and 40 hours in labour of their first child, and delivered without aid, 1 woman in 34, instead of 92, the average of the whole, died; and 1 child in 5, instead of 18. If the woman have previously borne children, protracted labour becomes more dangerous, as it must generally have arisen from the state of the pelvis; for in the same period 1 woman in 11 died; but the loss of children was rather less, namely, 1 in 6. In the range of the next 10 hours, that is to say, if more than 40, and under 50, were allowed to elapse, 1 woman in 13, and 3 children out of 10, were lost. The conclusion is against delay. It is quite a mistake to suppose, that the application of the forceps by a careful practitioner is necessarily more painful or more dangerous than the efforts made by nature for the expulsion of the child in such cases. On the contrary, the sufferings of the mother are both shortened and diminished, and her subsequent safety ensured, whilst the life of the child is preserved, which otherwise would be lost. Doubtless the unnecessary and wanton use of instruments is strongly to be reprehended; but much and pretty long experience has convinced the writer of this article, that of the two extremes of premature and dilatory recourse to the forceps, the latter is by far the most dangerous, and the most to be dreaded. He is particularly happy to embrace the present opportunity of expressing his concurrence in the sentiments maintained on this subject by Dr. Hamilton, the justly celebrated professor who fills the obstetric chair in Edinburgh, and to whom the profession is indebted for many advantages, and for none more than his powerful recommendation of early recourse to instrumental aid.

To deliver precise rules for the time and manner of applying the forceps, which ought decidedly to be preferred to the lever, would require a more minute detail than is compatible with this work, nor is it perhaps necessary, as these are fully laid down in those elementary books which are in the hands of every practitioner. The following observations, however, may be useful:

1*st*, In every instance, where there is reason to apprehend a tedious or difficult labour, it is of importance to prevent the first stage from being unnecessarily protracted. When the pains are regular, but productive of little effect, the means already pointed out for procuring dilatation of the os uteri within a limited period, generally twelve hours, ought to be employed.

2*d*, If the delivery can be accomplished by the forceps, it is possible to apply the instrument whenever the os uteri is completely dilated, but not sooner.

3*d*, Although the last assertion be true, yet it is generally found that the more the head has advanced in the pelvis, the easier is the application of the instrument, with the exception of those cases where the head is firmly wedged in the pelvis In such cases it has been necessary to raise it up a little. When the ear of the child can be felt behind the pubis, when a considerable part of the cranium corresponds to the hollow of the sacrum, and the perineum is touched, or a little pressed by the head, the case may be managed with the forceps, without much difficulty.

4*th*, A rule has been laid down, that before we apply the instrument, we should allow the head to rest on the perineum for six hours; that is, that we shall delay to act for six hours after action has become easy. There is no rule more absurd, and less to be depended on, for we may sometimes delay much longer; and in other cases, be required to deliver much sooner.

5*th*, We never ought to allow the head to remain long impacted, that is, much pressure to continue for a length of time on the soft parts, nor ought we to permit the uterine action to become exhausted, far less the general strength to be much impaired. If we do, uterine hemorrhage succeeds delivery, or inflammation comes on after it, or the uterus is ruptured; and, in the case of impaction, if the patient escape this risk, she is liable to sloughing of the soft parts, particularly of the urinary organs. Continued pressure produces swelling of the soft parts in the pelvis, which impedes delivery. It is preceded by heat and dryness of the vagina, which indicate inflammation coming on, and, if delivery be not resorted to, the case is likely to prove fatal.

6*th*, Whenever we find that the head is remaining stationary for several hours, and the uterine efforts doing no good, although frequent and painful, and when the ordinary means advised in tedious labour prove of no avail, we are warranted to interfere. A prolongation of suffering would only endanger both mother and child. It is no reasonable objection to this, that we find women continue in severe labour for some days, and yet not only bear the child without aid, but recover well. The fact is undoubted; but, on the other hand, it is no less certain that a great many such cases end fatally. It is quite impossible to say where the limits of safety end, or to lay down a general rule with respect to time. Regard must be paid to the strength and constitution of the patient, her age, to the circumstance of her being in labour for the first time, the fatigue endured, the effect of the pains, and the inefficacy of other means. Let us ascertain what the powers of nature can do so long as we safely may wait, and neither interfere rashly, nor delay dangerously. The combination of other evils or accidents adds to the urgency of the case.

7*th*. When it is quite ascertained that the pelvis is considerably contracted, we ought to deliver as soon as the head comes into a favourable place. The patient, in all probability, shall have had labour sufficiently severe, before the head have entered so far into the pelvis, and permitting labour to continue longer, is only adding unprofitably to her sufferings.

8*th*, If the pelvis be contracted, and especially if this state be combined with spasmodic action of the uterus, the head may be very long of entering the pelvis, or may never descend so low as is supposed in the third remark. In such a case, it becomes necessary to determine whether the forceps can be applied, or the child must be destroyed, by opening the head, and using the hook or extracting pincers. In the middle of the last century, long forceps was used by Dr. Smellie and others, when the head was high. On the Continent, the late excellent practitioner, Baudelocque, was, and the present energetic Dr. Osiander is, successful in this mode of using the forceps, which also has been advised by Dr. Hamilton, who, like Smellie, uses both a long and a short pair. In doubtful cases, an attempt certainly ought to be made to save the child; but repeated and irritating efforts are to be discouraged; nor, in any case, are they admissible, when the conjugate diameter is determined to be only three inches. The writer has seen persevering efforts made with the best intention, but ending at last in the use of the crotchet, and in the accession of inflammation, even before the delivery of the child.

9*th*, The blades of the forceps are to be successively introduced along the opposite sides of the head, sliding gently, and with the utmost tenderness. They are to be accurately and cautiously joined, and having ascertained that the application has been properly effected, and the fixture is secure, extraction during a pain, or at intervals, if the pains have gone off, is to be made in the direction of the axis of that part of the pelvis through which the head is passing. In doing this, time is to be considered as better than force.

Order Second.

The necessity for mutilating or destroying the child, can only arise from a mechanical cause, and almost uniformly from great contraction of the pelvis. When this is occasioned by tumours, these may frequently be extirpated; but when it proceeds from an alteration in the figure of the bones, the perforator ought to be employed as soon as it is ascertained that a living child cannot pass, and afterwards, if necessary, the crotchet is to be applied. Where great deformity is known to exist sufficiently early, the practice of inducing premature labour ought in preference to be adopted. A living child, at the full time, cannot pass, if the conjugate diameter of the pelvis be only three inches.

CHAP VII.

Of Impracticable Labour.

Some have rashly asserted, that in every case delivery might be accomplished by breaking down the child, but it is more sober minded to place very little reliance on this opinion. There can only be two modes of effecting the delivery of a child, the first through the pelvis, the second, by making an incision into the uterus, in those cases where the first mode is impracticable. This, which is known under the name of the Cesarean operation, is one of much simplicity, and very easly performed, but one of the utmost danger, not to the child, but to the mother. This danger arises from two sources, exhaustion produced by irritation or injury, consequent to the exposure of the abdominal cavity; and peritoneal inflammation, which is the most frequent of the two. There is at present only one instance where the mother has survived in Britain, but many successful cases have occurred on the continent, in consequence of the operation being there performed earlier, and under more favourable circumstances. In the latest case which is published, Dr. Locker, at Zurich, saved both mother and child. In Britain, the delivery of the woman would have been performed with the crotchet, as the life of the child is never put in competition with that of the mother, which is so greatly hazarded by the Cesarean operation.

CHAP. VIII.

Of Complicated Labour.

Order first.

When labour is complicated with uterine hemorrhage, no time ought to be lost in delivering the child, if the discharge be considerable. This is to be effected, either by turning or by using the forceps, according to the stage. No reliance can be placed in any serious case on the practice of rupturing the membranes.

Order Second.

When hemorrhage takes place from the vessels of the stomach or bowels, but particularly of the lungs, it is evident that a prolongation of labour cannot fail to be dangerous. Delivery ought to be accelerated, and indeed can seldom be trusted to the natural efforts. The lancet and other ordinary means of cure must also be resorted to.

Order Third.

If the paroxysm be repeated or severe, we must deliver, and employ cordials. It is also indispensable that the abdomen be properly compressed after the expulsion of the child.

Order Fourth.

The most frequent kind of puerperal convulsions is the epileptic, if we retain the nosological definition of Cullen, who includes under epilepsia the eclampsia or acute clonic spasm of Sauvages, one species of which is the *eclampsia parturientium.* They are generally preceded by headach and other symptoms of determination to the head, and are usually very severe and frequently repeated. Indeed, in many cases, they recur with the regularity of labour pains. Sometimes there is only one paroxysm, and the patient, without any interference whatever, goes on safely, but this result can never be depended on, and it is to be feared that the more probable termination would be fatal apoplexy, or a destruction of the vital principle during the severe convulsions which are excited. Two causes contribute materially to the production of this disease; the first is an undue determination of blood to the head, either by predisposition or by a peculiar state of the nervous system, excited by the condition of the uterus. The second is a costive and loaded state of the bowels, which operates powerfully on the brain. From this view it is easy to see, not only in what the prophylaxis, but also the treatment should consist. The lancet is to be powerfully and freely employed, the bowels are to be opened by a smart clyster, and if these means, particularly the former, carried as far as prudence dictates, do not put a stop to the disease, delivery must be artificially accomplished.

Order Fifth.

Rupture of the uterus, during labour, may undoubtedly take place suddenly and unexpectedly, but in most instances it is owing to mismanagement, particularly to delaying too long the use of the forceps, or allowing the child to remain in an unfavourable position without rectifying it, or to violent and injudicious attempts to turn the child when the uterus is acting strongly. The child usually escapes through the laceration into the cavity of the belly, the labour pains cease, great restlessness and sickness, vomiting, with rapid diminution of strength succeed, and generally within a few hours the sufferer is carried off. Peritoneal inflammation often comes on most rapidly, but it is possible for death to be caused by mere exhaustion, and sinking from abdominal irritation.

The best practice, generally speaking, is to introduce the hand through the laceration, and bring away the child by the natural passage.

Order Sixth.

The danger arising from suppression of urine is too obvious to require any reasoning to enforce the necessity of attention to this point in every case of tedious labour. When the catheter cannot be introduced, or relief obtained by cautiously raising up the head of the child, this complication calls for the cautious application of the forceps, at a period earlier perhaps than we would otherwise be led from the state of the pains and other circumstances to recommend.

Part III. OF THE PUERPERAL STATE.

CHAP. I.

Of the Management immediately after Delivery.

When the after-birth is expelled, it is too much the practice with many to sit up in bed immediately, and have the clothes shifted. Most alarming floodings, and other bad consequences, may result from this. The first thing to be done is, very slowly to remove the wet sheet from below the patient, she next turns slowly on her back, and has a bandage applied so firmly round the belly as to give the feeling of a pleasant support. The bandage often consists of a broad towel folded double, but it is better to have one made of stout cotton cloth, with tapes to tie, or buttons, with two rows of holes. It is prevented from slipping upwards and wrinkling by a thigh-piece, and in some cases it may be necessary also to have a shoulder strap. Many, with advantage, apply under this a compress, made of a napkin or quilted pad. The bandage being applied, a flannel petticoat, open in the middle, is next put on, and wrapt round the limbs, and a soft napkin is to be applied to absorb the discharge. If the patient be fatigued, no more is to be done, but if she be not, an aired shift and bedgown can be put on, and she is laid to rest; but if a half shift be used during labour, there is seldom great occasion to change it, for several hours at least. Although we are thus cautious respecting speedy shifting on account of the effect often produced by slight exertion, especially after a lingering labour, or in delicate women, yet the necessity of changing the clothes, as soon as prudence will permit, ought to be inculcated, and afterwards shifting every day, and having the discharge washed away, morning and evening, with a sponge and lukewarm water. The number of bed-clothes must be regulated by the season, but they never should be so many as to promote sweating, which weakens the patient, and gives a tendency to catch cold. It is usual to give some cordial after delivery, such as brandy or cinnamon-water. Unless the strength be exhausted, there is seldom occasion for this, and it often does harm. A little wine and water may be given if fatigued, or a little panado with wine; or if the labour have been lingering, and there is much langour, a little Madeira wine, without water, is very proper.

A stool should be procured within thirty-six hours after delivery, by means of a suitable dose of magnesia, or a little castor oil. If the patient is not to nurse, the laxatives should be rather brisker.

The urine should always be passed within twelve hours, at farthest, after delivery, and if there be any difficulty in voiding it, fomentations will be useful. After a severe labour, it is necessary to be very attentive to the voiding of the urine, and the state of the soft parts.

The diet ought to be light, and should consist, for the first two days, of tea and cold toast for breakfast, beef or chicken soup for dinner, and panado for supper. Afterwards a bit of chicken may be taken for dinner, and, as recovery goes on, the usual diet may be returned to. In these directions, however, regard must be had to the previous habits and present state of the patient.* The drink at first should be toast water, and malt liquor is, for some days, to be avoided; wine, or wine and water, may then be allowed, if no fever be present, and the weakness or former habits of the patient require it. In a good recovery, the patient may have the bed made on the third day, but, during the time, she should recline on a sofa. In a day or two longer she may be allowed to be dressed and sit a little, but ought not to walk about or leave the room for some time; and, even in summer, should not go out for an airing in less than three weeks. Many, before this time, do rise, and even attend to domestic cares earlier, but they often suffer very much, either from a weakening discharge, or a falling down of the womb.

CHAP. II.

Of Tremor and Fainting Fits.

It is not unusual for women, very soon after delivery, to be seized with a violent shaking or shivering, sometimes in consequence of rash and sudden exposure to cold, after being heated with the exertion of labour, but often from no evident cause. Nothing, in general, gives so speedy relief as a pretty large dose of laudanum, forty drops, for instance, in peppermint water, or in a little brandy and water. At the same time, the patient is kept in perfect rest, and when she is inclined to shake, she must be held gently by an assistant, so as to prevent her from doing so in a great degree. If she feel cold, and the teeth chatter, the application of a warm cloth to the stomach and feet is useful. This is not a dangerous, and seldom an obstinate, affection. If it, however, should be prolonged, camphor is of service.

Fainting is always an alarming symptom, and when it occurs, the first thing to be ascertained is, whether there be a great discharge or flooding, in which case the danger is extreme, and the treatment of this has been already pointed out. It may also attend inversion of the womb. But some women are, after a tedious and severe labour, and others even after very little suffering, liable to a short and temporary exhaustion, approaching to a fainting fit, or very often to that kind of insensibility or lowness, which occurs in a hysteric attack, and like it, this is frequently preceded by an involuntary crying or sobbing, immediately after the birth of the child. This hysterical lowness is not dangerous; indeed, there is never great ground for alarm, whilst the pulse continues, and there is no discharge, for in this case the patient may rather be said to be in a state of stillness and quietness than fainting. In those cases where this state occurs after delivery, a few drops of oil of cinnamon on sugar are useful, or we give thirty drops of laudanum in a little brandy, or hartshorn and water, whilst a free circulation of air is to be preserved. Volatile tincture of valerian is recommended by Dr. Hamilton to be given, as soon as the child is born, to those who are subject to fainting fits, and certainly is a useful remedy.

Actual syncope is much more alarming, even when it does not proceed from hemorrhage, great fatigue, or any other evident cause. There have been instances of sudden death following an easy labour, and in which no sufficient cause could be ascertained by dissection. The ordinary means of exciting the nervous and vascular system must be resorted to, and persevered in.

CHAP. III.

Of After Pains.

After pains are sometimes extremely troublesome during the first three days after delivery, and may even be more distressing than those of labour. They proceed from different causes, but the most frequent is the contraction of the womb to acquire its original size, and expel clots. This often occasions irregular grinding pains in the lower part of the belly, and sometimes in the back, like those of labour. They are usually accompanied with the discharge of clots of blood, and frequently are renewed for a day or two, whenever the child is applied to the breast. They are most effectually relieved by a full dose of laudanum, and warm fomentations. Gentle laxatives, and uniform pressure externally, contribute to relief. Another kind is accompanied with wind in the bowels. The pain is not merely felt in the bottom of the belly, but in different parts, and comes on often like gripes or cholic pains,

* As in many women there is a considerable disposition to fever and increased arterial action, animal food and wine or malt liquor, should be avoided, until the secretion of milk is fully established, and all symptoms of fever have disappeared. J.

sometimes accompanied with a little fulness of the belly, and pain on pressing hard. This is relieved by a clyster to open the bowels, afterwards a dose of laudanum in peppermint water, and fomentations. An injection, containing laudanum, is also useful. Sometimes worms cause this pain. Severe pains between the ribs and haunch hone may attack in paroxysms, continuing for more than half an hour, and then going off completely. These may be accompanied with quickness of pulse, and the urine is high coloured. They are relieved by opiates, fomentations, sinapisms, and laxatives; and sometimes a pretty firm bandage gives temporary relief. Constant pain, accompanied with shivering, vomiting, swelling, and tenderness of the belly, fever, and suppression of the cleansings, indicate inflammation, and require the earliest attention.

CHAP. IV.

Of Displacements of the Uterus.

Pain in the back and lower part of the belly, with a strong beating down, weakness, feeble pulse, and discharge of blood, require examination, lest the womb be inverted. If much time be lost, the inversion may either prove quickly fatal, or remain during the whole of life.

If the uterus be inverted, examination detects a fleshy tumour filling the vagina, whereas, if the womb be properly situated, the vagina is free, and the os uteri is felt open and empty. When the inversion is complete, the uterus is protruded altogether, and forms a fleshy mass, which projects externally. In either case, it must be immediately reduced by moderate pressure, and in general this is easily accomplished. When it has been neglected and becomes chronic, extirpation has in different instances been practised, on account of the injurious effect produced by the repeated hemorrhages, mucous discharges, and continued irritation attendant on this state. Some of these have succeeded perfectly; and in one the author saw the patient in perfect health many years after the operation.

It must next be observed, that in consequence of weakness and relaxation, or of rising and walking too soon, the womb, being yet heavy and large, may sink too much in the vagina, or may even come to protrude externally. This, in the first degree, is called a bearing down of the womb, and where it proceeds so far as to appear outwardly a procidentia uteri; but this extreme degree fortunately seldom happens at first. The patient for a length of time complains of weakness, and pain in the back, a sense of dragging about the loins, weariness and aching about the thighs and lower part of the belly, and unpleasant sensations when she attempts to walk, particularly a bearing down; and by and bye, when the womb descends lower, she cannot make water easily, and in the whole progress of the complaint the stomach and bowels are apt to be disordered, both in their functions and sensations. These affections of the bowels and stomach are very often prominent symptoms, leading off the attention of the patient from the true cause, which sometimes can only be discovered by the examination of a skilful practitioner.

This is a complaint which generally proceeds from relaxation, or from some exertion before the womb has returned to its usual size, or from its remaining for a length of time larger than usual. This naturally suggests a caution against rising too soon, or making any early exertion; and it is peculiarly incumbent on those who are delicate in constitution, or enfeebled by previous disease, to be on their guard in this respect. Although, doubtless, rash management on the part of the midwife may occasion this complaint, yet it is much oftener the fault of the patient herself. It must also be impressed on the mind, that it may succeed a miscarriage, or may even occur in unmarried women, from excessive discharge, fluor albus, or violent exertion, when out of order. Rest in a recumbent posture is of the greatest service in the early stage. The bowels are to be kept in a very regular state, by daily doses of Cheltenham salt, or sal polychrest, or any other mild laxative, in order to lessen the quantity of circulating fluid; and for the same purpose liquids ought to be avoided, that the uterus may speedily diminish in size and weight. The diet should be such as tends to increase the strength, and for the same purpose, in a month after delivery, the cold bath may be employed, if no particular symptom forbid it. The application of a proper bandage round the whole belly, with a moderate degree of firmness, often gives great relief to the uneasy feelings; and the early use of a compress over the uterine region, so as to excite to absorption, may be useful. Astringent injections tend to contract the vagina, and are sometimes of benefit. If these means fail, then we must employ a pessary. This is a complaint which is apt to be increased during the first three months of subsequent pregnancy, but after the third month it disappears.

There is another affection which may be confounded with this, namely, a relaxation and protrusion of the vagina itself. This forms a soft swelling or prominence at the orifice of the vagina, which sometimes completely encircles the opening, but oftener is more on the one side than on the other, or is greatest behind. It gives no particular inconvenience, unless it exist in a great degree, and it usually disappears on going to bed. It requires the use of astringent decoctions, or alum water, externally, or employed as injections, and the frequent application of cold water, by means of a sponge. Internal astringents, such as tincture of kino, have been thought useful. If the patient be weak, strengthening remedies are proper, such as bark, steel, the cold bath, &c. In this, as well as in the former complaint, it is of great service to support the perineum permanently; the best mode of doing which, is by an elastic steel truss similar to that used for prolapsus ani.

CHAP. V.

Of Irregularities of the Lochial Discharge.

An increased, and sometimes a continued discharge, after delivery, is often the consequence of getting up too soon, or making some early exertion. It is usually attended with pain in the back, and always produces weakness. It is to be removed by avoiding exertion, taking some strengthening medicine, such as bark and wine, and using, if it continue, the shower-bath. The aching pain in the back is often removed by the applition of an adhesive or warm plaster.

The lochial discharge is in some women very trifling, and may even stop very soon without any bad effect. But when it is suddenly checked by exposure to cold, or other causes, most painful consequences may follow, such as swelling of the belly, great pain, sickness, and fever. These symptoms are dangerous at all times, but are still more to be dreaded, as they often attend inflammation, and indeed the two cases can only be distinguished by minute attention. A purgative clyster should be instantly administered, a cloth, soaked in oil of turpentine, or hot fomentations applied to the belly, and a perspiration encouraged by a saline julep, containing antimonial wine, together with tepid drinks. An anodyne clyster is also useful, and if the pain continue, the lancet must be used. In this disease, the suppression of the discharge is an effect rather than a cause, and indeed does not uniformly take place, for the symptoms arise from spasm of the uterine fibres. This differs from inflammation in coming on most suddenly; the pain from the first is severe, but it remits, or sometimes for a few seconds goes entirely off. But it must not be supposed that this state can continue long without exciting inflammation.

Ill-smelled discharge proceeds from clots of blood lodging about the womb, and requires strict attention to cleanliness; it may even be necessary to wash the discharge from the passage, by means of a syringe. If, however, this discharge be attended with sickness or nausea, quick pulse, hot skin, parched hands and feet, thirst and want of appetite, or repeated discharges of blood, and pain in the lower part of the belly and back, then there is reason to conclude that part of the after-birth remains in the womb, and great attention is necessary to preserve the patient. This affection often passes at first for a weed.

The patient is worn out by nocturnal perspiration, fever, and want of nourishment, until at length a putrid mass is discharged from the womb, perhaps about the ninth or tenth day, or even after some weeks of suffering, and then the patient generally recovers.

The bowels are to be regulated, either by laxatives or opiate injections, according to their state. The diet must be light, such as chicken broth, beef tea, calf's-feet jelly, arrow root, &c. The elixir of vitriol is useful for promoting appetite and checking perspiration. Camphorated mixture is of service for allaying nervous affections. Great attention must be paid to cleanliness and ventilation. Astringent injections have been employed, and sometimes with advantage.

CHAP. VI.

Of Swelled Leg.

After delivery, one of the legs is sometimes affected with a painful swelling, which is often, though not always correctly, attributed to some violence in the labour, or some imprudence afterwards. It makes its appearance about ten days after delivery, sometimes sooner or even later. It begins with fever, and pain in the back, or lower part of the belly, particularly about the groin, where there is considerable stiffness felt. The pain may gradually extend down the limb, but more frequently it is, after these symptoms, suddenly felt in the calf of the leg or knee, and presently the whole limb, which formerly perhaps was cold, becomes hot and swelled. The acute pain slowly abates, but the limb continues tender, and can scarcely be moved. The pulse becomes much quicker, the face pale, the strength is greatly impaired, and frequently very copious perspiration adds to the weakness.

The duration of this disease is variable, but in general it is considerable, and occasionally after one thigh becomes better, the other becomes affected with similar symptoms. In one case, which lately was attended by the author, the inferior and both superior extremities were successively attacked. The complaint in the upper parts was preceded by pain and stiffness in the side of the chest. There is always great debility attendant on this disease, and even a tendency to syncope.

The treatment consists in the immediate application of leeches, or of hot solution of acetite of lead to the groin, at the same time that a purgative is administered. If the symptoms go on, and the limb becomes affected and swelled, relief is sometimes obtained by rubbing with camphorated oil, or tincture of soap and opium;* but fomentations with hot water are more generally useful. At the same time the bowels are to be kept regular with cream of tartar, and sleep procured by anodynes.† When the acute symptoms are over, and the limb only remains weak, friction with the flesh-brush is proper, and a roller should be applied with moderate firmness from the toes to the groin. The cold bath is useful to re-establish the health. The diet ought, after the inflammatory symptoms have abated, to be nourishing, and the re-establishment of the health is promoted by removing to the country. Tonic medicines at this period are also useful.

CHAP. VII.

Of Ephemeral and Remittent Fevers.

Women, who are disturbed much in their repose, who have suffered greatly during labour, who have very sore nipples, who are inattentive to their diet, distressed in their mind, or exposed to cold, are liable to an attack of fever, called in this country a weed. The fit begins with chillness, cold feet, and violent trembling; pain in the back, headach, and in some instances, inclination to vomit. Presently flushes of heat are felt, which at last become steady, and the patient feels extremely hot and restless. In some time afterwards, perspiration breaks out, continues for a considerable time, and at last abates, leaving the patient free from fever, but very languid. During both the cold and hot stage, the pulse is frequent, and there is thirst; but in the sweating stage both these symptoms decline. The whole fit is usually finished within twenty-four hours, frequently in a much shorter period. There may be only one attack, but it is not

* The unguentum stramonii has sometimes been used advantageously.

† In some cases the disease has only yielded to the use of mercury, carried so far as to touch the mouth. J.

uncommon for the fits to come on every day for more than a week, nearly about the same time, or an hour sooner or later each day; and in that case they are preceded by coldness in the back, accompanied with aching pain. In this state the stomach becomes filled with wind, the bowels are bound, and the patient is timid or hysterical. In some instances there is a state of complete apyrexia, in others only a remission of the symptoms. Short attacks of this fever are not in general dangerous; but if they be repeated and prolonged, it is probable that they depend on, or are kept up, by some local disease. There may be incipient and obscure disease in some of the great cavities of the body, or the mammæ may be partially affected. In all such cases it is therefore necessary to examine minutely into the symptoms and sensations, for it has happened that some patients have been suddenly cut off, who were supposed to be in little danger.

When the cold fit comes on, our object is to hasten the hot one, which is done, not by putting many bedclothes on the patient, for these are hurtful, but by giving frequently a small quantity of some warm drink, such as gruel or lemonade, and applying a bottle, filled with warm water, to the feet and pit of the stomach, or to the back, if it feel cold. When the hot fit is established, these applications are to be removed, and the tepid drinks continued till the sweat comes out. Means are not to be employed for pushing this far, but by taking a very little drink, and lying quiet for some hours, it is to be encouraged to continue in a moderate degree, till all the uneasy feelings and feverish symptoms are removed. Then warm dry linen is to be put on, and cold avoided with care. It requires much prudence to say when the perspiration ought to be checked, but it is a good general rule, to continue it till the fever is removed. After the sweating is over, a little panado with wine is proper. A repetition of the fever is to be prevented, by avoiding those causes which first brought it on, keeping the bowels open, taking some strengthening medicines, such as bark, and procuring rest by opiates. When there is a tendency to return, and no local disease can be detected, the fit is sometimes checked by taking twenty-five drops of laudanum an hour before the expected time of attack, and applying warm flannel to the back. During the intervals, infusion of bark, or the cautious use of arsenic, will be useful.

If palpitation occur frequently, either along with this fever or without it, the best remedy is a large dose of laudanum, in a glass of peppermint water, and during the interval, the volatile tincture of valerian, with laxatives, or the camphorated mixture, will be proper.

If the attacks of fever be repeated, or if it become continued, it will be necessary to give up nursing; and indeed in many cases the secretion of milk becomes so much diminished as to render it impossible for the child to be nourished by the parent. When local pain, or symptoms indicating the existence of inflammatory action in any organ appear, no cure can be expected till that organ be relieved.

CHAP. VIII.

Of Milk Fever.

The secretion of the milk is often accompanied with a considerable degree of fever, called the milk fever. This is partly owing to that disturbance which is always to a certain degree excited in the system, whenever a new process is established, and partly owing to the swelling or irritation of the breasts themselves. In this view, it may, though of short duration, be compared to the teething fever of infants. This fever commences about the second or third day after delivery, and consists of a cold, a hot, and a sweating stage, during each of which, the symptoms are so much the same with those described under the name of weed, or ephemeral fever, that it is needless to repeat them. It must not, however, be supposed, that the fever takes place in every instance, more than that every child has a teething fever: and even in those cases where the fever is considerable, there is very little danger. There can be no difficulty in distinguishing this disease, for the breasts are full, hard, and painful, circumstances which at once point out the nature of the complaint. By way of preventing this fever, it has been recommended, that the child be applied to the breast as soon after delivery as the strength of the patient will permit, and this is extremely proper if the trial be made in such a way as not to fatigue her. It is also useful to procure a stool early, and it is even proper, where the patient is stout, of a full habit, and does not purpose to nurse, to give laxatives more freely, in order to diminish the quantity of milk, and prevent swelling and irritation of the breasts.

When milk fever does take place, the treatment is very simple, consisting in giving warm drink, such as gruel, or lemonade, in small quantity during the cold stage, and applying warm flannel to the feet and stomach. In the hot stage, the curtains are to be thrown open, the coverlet taken off, and tepid drink, with gentle diaphoretics, given to excite perspiration. In the sweating stage, the perspiration, which is generally sour-smelled, is to be gently encouraged, till it be universal, and the patient feel relieved, then it is to be lessened, and the management is the same as in weed. These means are to be employed to an extent, and with a degree of attention, proportioned entirely to the severity of the symptoms.

CHAP. IX.

Of Inflammation of the Breasts.

When, in consequence of exposure to cold, or of the pain and tension, occasioned by the retention of the milk, in those who do not, or cannot suckle, inflammation of the breast is excited, there is great reason to apprehend that suppuration will take place. This disease is easily known by the pain, hardness, and swelling which accompany it. In some cases, the whole breast seems to be affected, in others, only one half, and in many the affection is more circumscribed, or small and superficial. This complaint is generally accompanied by fever, and that is sometimes smart, when the mammary affection is so obscure as to escape observation for several hours, or even for a day or two. When the breast inflames, it is evident that the retention of the milk must, for a time at least, increase the pain. The first and earliest object, therefore, must be to have the breast gently drawn, either by the child or by other means, provided these attempts do not give pain, for if they do so, and the milk do not come readily, more hurt than good will be done. The breast should be gently fomented with a sponge dipped in tepid water, and then covered with a poultice of bread and milk, so as to continue the soothing effects of the fomentation. The patient should keep in bed, and have the breast properly supported. Spare dry diet and laxatives are proper. If the pain and hardness do not very soon go off, but, on the contrary, the former becomes more severe and throbbing, suppuration must take place, and it is to be encouraged by bread and milk poultices, applied hotter than formerly. If the abscess be small and superficial, the spot soon becomes red, and at last breaks, occasioning, comparatively speaking, little distress, and scarcely giving any interruption to nursing. But if it be deeper, or more extensive, and the glandular part of the breast be affected, all the symptoms are more severe, the progress is tedious, and the strength is apt to be reduced by fever, perspiration, and want of appetite. In these cases, if the abscess do not point and break soon, no good can be gained by delay, an opening should be made so as to evacuate the matter freely. This not only gives immediate relief, but prevents a farther extension of the mischief, and the foundation of future disease. In every instance, a free opening should be procured for the pus, and if sinuses form, these must be opened completely and at once. In unhealthy inflammation of the breast, different glands may successively be affected in both breasts, and slow abscesses form, which produce troublesome sinuses when they burst. In all such cases, it is necessary daily to examine the breast, for the constitution is apt to be undermined by repeated attacks of shivering and fits of fever. The stomach is impaired, anorexia and reaching take place, and a fatal cachectic state is produced. These shiverings are removed by opening the abscess, or evacuating the confined matter, and the general health is restored, by laying open any sinuses which may form. Light nourishment, with a liberal proportion of wine, varied tonics, and the use of opiates and laxatives, according to circumstances, are proper. Indurations or local affections from torpidity are benefited by a gentle course of mercury. When the patient can take nourishment, there is seldom any great danger; but if she have a perpetual and intractable loathing at food, with diarrhœa, and especially if she be of a strumous habit, there is much ground to fear ultimately a fatal issue. In some instances the mesenteric glands, in others the uterus itself, are affected in the course of the disease, which may be protracted for some months.

CHAP. X.

Of Uterine Inflammation.

Inflammation of the womb usually begins between the second and fifth day after delivery, but it may take place at a later period. It is pointed out by a pain in the lower part of the belly, which gradually increases in violence, and continues without intermission, though it is subject to occasional aggravations. The uterine region is very painful when it is pressed, and it is a little swelled. There is, however, no general swelling of the abdomen with tension, unless the peritoneum have become affected. But the parietes are rather slack, and we can feel the uterus distinctly through them to be harder than usual, and it is very sensible. There is also pain felt in the back, which shoots to the groins; and there is usually a difficulty of voiding the urine, or a complete suppression, or distressing degree of strangury. The situation of the pain will vary according to the part of the uterus first and principally affected. The internal parts become also frequently of a deep red colour, and the vagina and uterus have their temperature increased. The lochial discharge is very early suppressed, and the secretion of milk diminished or destroyed. Nearly about the same time that the local symptoms appear, or perhaps a little earlier, the system becomes affected. The pulse very early becomes frequent, and somewhat hard. The patient is chilly, or has a shivering fit succeeded by increased temperature of the skin, and it is not unusual for her to be sick, or to vomit bilious fluid. The tongue is white and dry, and the urine high coloured and turbid. The vomiting in some cases continues, and the bowels are at first bound, but afterwards the stools are passed more frequently. If the peritoneum come to partake extensively of the disease, then we have early swelling and tenderness of the abdomen, and the danger is greatly increased.

This disease calls for the early and free use of the lancet, which is the principal remedy; and the number of times that we repeat the evacuation, must depend upon the constitution of the patient, the effects produced, and the period of the disease. If three or four days have passed over, the pulse may be full and frequent; but this is an indication that suppuration is going on, which will be ascertained by throbbing pain, &c. In this case the lancet is hurtful. Mild laxatives are also highly proper. Fomentations are very useful, and external irritations are likewise of benefit after the acute stage has been subdued by the lancet. The application of oil of turpentine is perhaps as useful as any other that can be made. Diaphoretics ought to be administered, such as the saline julep, with the addition of antimonial wine and laudanum. This is the best internal remedy we can employ. Emollient clysters, or sometimes anodyne clysters, give relief. In the suppurative stage we must keep the bowels regular, give light nourishment, apply fomentations, and allay pain with anodynes. When the matter is discharged, a removal to the country will be useful, and tonic medicines should be given.

CHAP. XI.

Of Peritoneal Inflammation.

The peritoneal lining of the abdomen, or the covering of the intestines, may be inflamed alone; or this disease may be combined with inflammation of the uterus.

Peritoneal inflammation may be caused by violence during delivery, or the application of cold, or the injudicious use of stimulants. It may not come on for three weeks after delivery, but it usually commences on the second day, and earlier than inflammation of the womb; and it may often be observed, that the pulse continues frequent from the time of delivery. It is preceded or attended by a shivering and sickness, or vomiting, and it is marked by pain in the belly, which sometimes is very universal, though, in other cases, it is at first confined to one spot. The abdomen very soon becomes swelled and tense, and this state rapidly increases. The pulse is frequent, small, and sharp, the skin hot, the tongue either clean, or white and dry; the patient thirsty, she vomits frequently, the milk is not secreted, and lochia are frequently obstructed. These symptoms often come on very acutely, but it ought to be deeply impressed on the mind of the reader, that they may also approach insidiously. Wandering pain is felt in the belly, neither acute nor altogether constant. It passes for after-pains, but it is attended with frequency of pulse, and some fulness of the belly, and a little sickness. But whether the early symptoms come on rapidly or slowly, they soon increase, the belly becomes as large as before delivery, and is often so tender, that the weight of the bed-clothes can scarcely be endured; the patient also feels much pain when she turns. The respiration becomes very difficult, and sometimes a cough comes on, which aggravates the distress, or it exists from the first, attended with pain in the side as a prominent symptom. Sometimes the patient has constant belching, and brings up mouthfuls of fluid, which always gives pain. The bowels are either costive, or she purges bilious or dark-coloured fæces. These symptoms are more or less acute, according to the extent to which the peritoneum is affected. They are at first milder and more protracted in those cases where the inflammation begins in the uterus; and in such the pain is often not very great nor very extensive for some time. If the disease is to prove fatal, the swelling and tension of the belly increase, so that the abdomen becomes round and prominent, the vomiting continues, the pulse becomes excessively frequent and irregular, the fauces are apthous, death is marked in the countenance, the extremities cold, and the pain usually ceases rather suddenly. The patient has unrefreshing slumber, and sometimes delirium mite, but she may also remain sensible to the last. The disease usually proves fatal within five days, but may be protracted for eight or ten days, or even longer.

The practice in this disease is very limited, but very important. It consists in an instant recourse to the lancet, which is to be used at first with freedom, but in more advanced stages with circumspection. If it is to prove useful, it will do so soon; and a frequent repetition toward the latter end can only hasten death. Whilst, therefore, the writer places his chief reliance on this remedy, he cautions against its abuse.

Fomentations are soothing and useful, and all the pained part of the abdomen ought to be covered with a cloth wet with oil of turpentine.

The bowels are to be opened by laxative medicine, and stimulants of any kind are to be avoided. Fruits and grateful drinks are to be prescribed.

CHAP. XII.

Of Puerperal Fever.

Puerperal fever begins sometimes in an insidious manner, without that shivering which usually gives intimation of the approach of a serious malady. In other cases, the shivering is perceived, and varies considerably in degree, being either slight or pretty severe. The first symptoms, independent of the shivering, are frequency of pulse, oppression, nausea, or vomiting, pain in the head, particularly above the eyebrows. The night is passed with little sleep, much confusion, and occasionally some delirium; but this is not common in the commencement.

It must not, however, be forgotten, that in many instances there is no headach in any stage of the disease, nor any sickness nor vomiting in the beginning. In some, the temper from the first is uncommonly iritable, in others there is much timidity, or listlessness, or apathy. Hysterical symptoms not unfrequently supervene.

From the beginning, or very soon afterwards, pain is felt in the belly; at first slight, but it soon increases, and in some instances the abdomen becomes so tender, that even the weight of the bed clothes is productive of distress. A general fulness, without tension of the belly, accompanies this from the first, and it usually increases pretty rapidly, and may proceed so far as to make the patient nearly as large as she was before delivery. In such cases the abdomen becomes tense, and the breathing is much oppressed; indeed, in every instance, the respiration is more or less affected; the free action of the abdominal muscles, which are concerned in that function, being productive of pain. The degree of pain, its seat, and period of accession, vary in different cases. In some it evidently begins in the uterus, and, coming in paroxysms, resembles severe after-pains, but never goes entirely off, and is accompanied with bearing-down. The uterine region is painful, particularly toward one side. The os uteri, if examined, is not much more sensible than usual. There is generally pain in the back. In other cases the pain is first felt about the lower part of the ribs on one side, and is accompanied with cough. The belly is tumid, and tender when pressed, but except then, or in turning, the patient complains little of it. Sometimes severe pain, like spasm, attacks the iliac region, and extends down to the thigh, and toward the pubis and bladder.

The face is sometimes flushed at first, or a patch of deep red appears on the cheeks, but the countenance in general is altogether pale, or at least not suffused, the eyes are without animation, and the lips and angles of the eyes are white. The whole features indicate anxiety and great debility. When vomiting occurs at the very commencement, it is generally bilious. In the course of the disease, it becomes so frequent that nothing will stay in the stomach; and, towards the conclusion of the fever, the fluid thrown up is dark-coloured like coffee, and frequently fœtid. This is a symptom which always, if it do not proceed from a morbid structure, indicates, in whatever disease it occurs, an entire loss of tone of that organ, and in this fever is a fatal symptom. But, to proceed with the history. There is, in many instances, great dejection of mind, and always langour, with general debility of the muscular fibres, and the patient lies chiefly on her back, or there is so much listlessness, that she sometimes makes little complaint. The skin is not very hot, but is rather clammy and relaxed. There are cases, however, where the patient complains of universal and oppressive heat, until toward the end, when the extremities become cold. In other instances the temperature varies, the patient being alternately hotter and cooler. The tongue is pale or white at first, but presently becomes brown, and uniformly apthæ appear in the throat, and extend down the œsophagus, and over all the inside of the mouth. From the irritability of the stomach and bowels, it is highly probable that these organs participate in the tender state, and the upper part of the larynx seems to be affected from the cough which is excited.

It has already been mentioned, that the pulse, from the first, is very frequent, and at that period it is fuller than in simpler peritoneal inflammation, but it soon becomes feeble. The thirst is not always great, at least the patient is often careless about drink. The bowels are often at first bound; but afterwards, especially about the third day, they usually become loose, and the stools are dark, fœtid, and often frothy. This evacuation seems to give relief. The urine is dark-coloured, has a brown sediment, and is passed frequently, and with pain. The lochial discharge continues for a time, but presently is diminished, has a bad smell. or is changed in appearance, or gradually ceases; and it is observable that the re-appearance of the lochia, if they had been suppressed, is not critical. The secretion of milk stops, and the patient inquires very seldom about the child. In bad cases, the swelling of the belly increases rapidly, but the pain does not always keep pace with the swelling, being sometimes least when the swelling is greatest, and in the end it generally goes entirely off. The breathing becomes laborious in proportion as the belly enlarges. The strength sinks, the pulse, always frequent, becomes weak and tremulous, the throat and mouth appear sloughy; perhaps the stools are passed involuntarily, and the patient usually dies about the fifth day of the disease, but in some cases not until the fourteenth, in others, so early as the second day. In some instances death is preceded by low delirium, or stupor; in others the mind continues unimpaired till within a few minutes of dissolution, and the patient is carried off after a fit of a convulsive kind.

This fever attacks generally on the second, and sometimes the third day after delivery; but it has also occurred so late as after a week. The earlier it attacks, the greater is the danger; and few women recover who have the belly much swelled.

On dissection there is found in the abdomen a considerable quantity of fluid, similar to that met with in peritonitis. The omentum and peritoneum are inflamed, but perhaps very slightly, and gangrene is unusual. The swelling is neither proportioned to the inflammation nor effusion, nor in every instance dependent on these, but on that inflation of the bowels which results from the relaxation of the muscular fibres of the bowels, which is so common in the puerperal state, particularly in puerperal disease. The uterus is not more affected than the intestines. In some cases the thoracic viscera are inflamed. There is the most satisfactory evidence that this disease is infectious, and also that it is epidemic over a greater or less extent of country in particular years.

As it has been confounded by many with peritonitis, it is not to be wondered at if very opposite modes of treatment should be proposed. This attempt to identify puerperal, or, as it has been called, low child-bed fever, with simple inflammation, is practically of the most mischievous nature, and ought to be resisted by all attentive observers of disease.

Early and copious venesection has been strongly advised, as the most effectual remedy; and in a disease which proves so fatal under any treatment, the author has felt it to be his duty, even under many doubts, to make a full and faithful trial of the plan. The result has completely convinced him, that copious and repeated bleeding is a most useless and a most dangerous practice; and if he can prevent his younger brethren from being led away by the plausible arguments which have been adduced in favour of the lancet, he shall have performed an important service to those who are attacked with the disease. He is not inclined to forbid altogether the detraction of blood, but he wishes to limit that practice to those cases where the symptoms of inflammation are the most decided, and particularly to those where the pain is fixed, as, for instance, in the side, or in the uterus; the lancet, in such instances, should be early employed, but ought not to be repeated, and where the symptoms are not decided, it should be altogether omitted. None have recovered who have been largely and repeatedly bled, although the blood was such as is met with in inflammation, and all the recoveries he has met with, have been amongst those who either were not bled at all, or only once, and sparingly.*

Laxatives, bark, and light nourishment, to support the strength, are the most useful internal remedies. In the more advanced stages, wine, to act as a cordial, and opiates, to allay irritation, will be useful. Blisters have been advised, but they are more injurious than beneficial. The application of turpentine is certainly of advantage, and in general gives more relief than fomentations.

If the patient recover, the bowels remain long in an irritable state, and require much attention.

CHAP. XIII.

Of Chronic Swelling of the Abdomen.

It is not unusual, if the patient be exposed to cold after delivery, or have any puerperal disease of an inflammatory nature, for the belly to become swollen and prominent, with some degree of tension. This tumefaction arises from inflation of the bowels, and is dependent on some disease of the uterine appendages, generally of one or both of the ovaria. The connection between the intestines and the uterus and ovaria is well seen, both in the early weeks of gestation, and at the menstrual period, many females about that time having the bowels much distended with air; and this very disease under consideration, may be produced by exposure to cold during menstruation.

It is a complaint of some importance, not only on account of appearance, but also as it indicates the existence of a local disease, or change of structure, which, at some future period, may prove formidable. It is sometimes succeeded by ascites, but much more frequently by that disease improperly called dropsy of the ovarium. In some instances, however, it seems to be entirely dependent on the state of the bowels, at least no other disease manifests itself in future life. When it is not symptomatic of organic affection of the uterine system, it may be sometimes removed by strict attention to the action of the bowels, which is kept up by aperient medicines, administered so as to invigorate, and not weaken the muscular fibres of the intestines. These medicines must be varied according to their effect, and may be combined with tonics, and uniform but

* With us the disease, in its first stage, may be generally considered as of a highly inflammatory nature, justifying copious depletion by venesection and cathartics. J.

moderate compression of the abdomen, or long continued friction every morning and evening.

When it is dependent on ovarian disease, the attention must be directed to the removal of that, which is a matter of great difficulty. The present excellent and zealous Professor of Midwifery in the University of Edinburgh, Dr. Hamilton, has informed the author, that he has, in some cases, been successful, by employing patting or friction externally, and prescribing the solution of muriate of lime.

This chronic swelling is not to be confounded with a tumefaction of a more acute nature, which sometimes occurs in the puerperal state, without pain, or indication of inflammation. The same experienced practitioner compares this swelling to a pillow of down, for, by pressing with the hand, a similar soft sensation is perceived: the hand sinks, but the swelling immediately rises on removing the pressure. It is considered as a fatal symptom.

CHAP. XIV.

Of the Signs that a Woman has been recently delivered.

It is sometimes an object of great importance in medical jurisprudence, to determine whether a woman have lately been delivered of a child. This can be done by examination of the breasts, the external appearance of the abdomen, and the condition of the uterus and vagina. We find the labia and vagina relaxed, somewhat tumid, and of a deeper red than usual. The perineum is generally injured, or the fourchette at least is torn. There is a sanguineous discharge. The uterus is felt to be enlarged, and has neither the shape of the gravid nor of the unimpregnated womb. It generally lies obliquely to one side. The os uteri is nearly circular, is soft, somewhat rugged, and will admit the point of one or more fingers, according to the time which has elapsed since delivery. The belly is prominent, and the integuments lax, wrinkled, and covered with light-coloured broken streaks. The breasts are enlarged, and contain milk, and have a very distinct and dark areola. Many writers on medical jurisprudence, however, consider these signs as fallacious. This, however, is one of the questions, it would appear, which can be more accurately determined by a man of plain sense than by a speculative philosopher. There have been instances where milk has been discovered in the breasts in the virgin state, at least so we are told by authors; but it would certainly be considered as no great proof of virginity, were a female to be found with abundance of milk, suckling a child.

One thing is certain, that the whole of the signs or appearances enumerated cannot exist without a previous pregnancy. A question naturally arises here, May they not be met with when the female has expelled a mass of hydatids, or a mole, as it has been called? This may be decidedly answered in the negative. Most of such substances are produced by conception, but after a time the ovum becomes blighted, and changed into hydatid, or a more solid disorganized mass. As pregnancy, therefore, has existed, it is evident that the secretion of milk and distention of the breasts may take place, and the uterus will be found enlarged. But it is very rare for these masses to acquire such a size as shall enlarge the uterus, or distend the belly, so as to produce such appearances as follow the delivery of a child. And as they are soft, we do not find the same injury sustained by the perineum, or external parts.

Certain cases of suppression of the menses are accompanied with swelling of the belly, and sometimes secretion of a milky or serous fluid in the breasts. But the abdominal tumour arises from inflation of the bowels, and, when removed, leaves no mark on the skin, and cannot have any effect on the state of the vagina, labia, or uterus. Ignorant people suppose, that in such cases of suppression the menses are really retained and accumulated in the uterus, and therefore may enlarge it. This can only happen when the vagina is closed, and in that case relief must be obtained by an operation, the performer of which can bear testimony to the nature of the case.

If in any one instance it could be established that a female had been large, as in pregnancy, and all the signs above enumerated were met with, and particularly when combined with laceration of the perineum, there cannot be a doubt. Granting that hydatids and blighted ova, or moles, could produce the other symptoms, they could not tear the perineum. If such substances really were expelled, they would be shown by the patient, or described by her, so as to satisfy a medical practitioner. Far less can mechanical obstruction of the menses occasion deception, for this cannot possibly injure the perineum, and indeed can only be removed by a surgical operation. Last of all, the absurd account often given by the patient herself must convince every intelligent practitioner of her guilt.

In cases where the mother is dead, and it is necessary to ascertain whether or not she has been delivered of a child, we have, in addition to those marks already described, an opportunity of examining the uterus and its appendages by dissection. The womb is found enlarged, its substance thickened, its cavity filled with coagulated blood, or, if empty, the internal surface is covered with a black coating of blood. The vessels are large, and as they are largest where the placenta was attached, marks corresponding to this attachment may for a time be observed. The extremities of the tubes, but particularly the ovaria, are highly vascular, and these latter contain, on different parts of their surface, vesicles filled with bloody fluid. Can it be determined by dissection, whether a female has had a premature labour, or have discharged a false conception, as it has been called? This is chiefly to be done by the state of the surface of the uterine cavity, and the size of the vessels. After abortion, or premature labour, there is usually some portion of decidua left, and the uterine vessels are large in proportion as the period has been advanced. In blighted ova, or false conception, on the other hand, there can be no portion left of healthy decidua; but, particularly, there cannot be expected the same enlargement of uterine vessels to support a fading or imperfectly organized mass, which would be requisite for a perfect and vigorous ovum. (J B.)

MIGRATION. See Birds Migratory, and Hybernation.

MILAN, a city of Italy, and the capital of that portion which was lately formed into the kingdom of Lombardy by the French, but which formerly constituted the Duchy of Milan. It is situated in a plain, between the rivers Adda and Ticino, from which it is watered by canals drawn from each. One of these canals was commenced in the year 1179, and rendered navigable in 1271: and the navigation is now advancing towards Pavia by a third. This city is about eight miles in circuit. Some of the streets are spacious, and built in straight lines; but many are narrow, crooked, and inconvenient. For the most part they are paved with small marble, or granite pebbles, from the bed of the neighbouring rivers and torrents.

Public buildings are numerous in Milan. The cathedral, standing nearly in its centre, for size and beauty, is considered the finest in Italy, next to St. Peter's at Rome.* It is an edifice in the genuine gothic style, of the largest dimensions, and consists entirely of pure white marble. It extends 490 feet in length, 298 in breadth; it is divided into five naves by 52 enormous marble gothic columns, and it is lighted by five cupolas. The height within under the principal dome is 258 feet; the arches corresponding to which, are 48 feet wide, supported by columns 8 feet in diameter. The pillars supporting the roof are above 90 feet high; and the roof itself is covered with blocks of marble, so closely cemented together by a hard and durable substance, as to appear one entire piece. The principal tower, crowned by a balcony, and ascended by 468 steps, is 400 feet high, affording a magnificent prospect of the city below, surrounded by a fertile country and picturesque mountains. Although this church was begun in the year 1386, the façade, presenting a great variety of ornaments, was never completed until Bonaparte, having resolved that it should be finished in an elegant manner, employed a great many workmen on it. About 4000 statues adorn the exterior and interior of the cathedral, some not exceeding a foot in height. One by the sculptor Agrati, represents St. Bartholomew, who was flayed alive, holding up his own skin as a drapery. It is of white marble, inscribed, *Non me Praxiteles sed Marcus finxit Agrati*, and is esteemed a *chef d'œuvre* of sculpture by the Milanese. But it would certainly be more suitable for an anatomical theatre, than to ornament the interior of a place of public worship. Two large pulpits occupy the sides of the chancel, and near them is a fine organ. Among the other more remarkable objects, is a subterraneous chapel, the place of sepulture of Cardinal Borromeo, Archbishop of Milan, who died in 1584. Seven bass reliefs of silver, forming seven sides of the chapel, represent the principal incidents of his life, executed in a masterly manner: and his body reposes in a shrine, formed of large pieces of glass, with edges of silver gilt. It is arrayed in his pontifical habit; the face exposed, and exhibiting a mortifying spectacle amidst so much grandeur. His hands, in silk gloves, hold a cross, ornamented with diamonds, and a brilliant crown is suspended over his head. The quantity of precious substances buried here exceeds belief. The treasury of the cathedral, besides, contains immense riches in precious stones, gold, and statues of massy silver. But a large proportion of the revenues having been withdrawn by the French, for more useful purposes than sustaining ecclesiastical pomp, the former splendour of this cathedral is diminished.

In its environs is the church of Santa Maria de Morti, a small oratory, which is entirely ornamented with pictures framed of human bones. The church of St. Ambrose, who was Bishop of Milan in the fourth century, and author of very voluminous works, is said to be reared on foundations coeval with himself. But the present structure belongs to the ninth century, and if its doors of bronze be of the same date, they must be different from those which that celebrated father closed against the emperor Theodosius. The pavement is of fine mixed marbles. The vault of the choir is of Mosaic; and the great altar under which the body of St. Ambrose rests, is supported by four beautiful columns of porphyry, enriched with precious stones. The other churches of San Vittore, Santa Maria della Grazie, San Lorenzo, San Celso, are remarkable for size, antiquity, architecture, or paintings. That of San Francesco Maggiore is the largest of the modern churches of Milan.

A considerable number of years ago, this city contained 50 monasteries and 62 nunneries. The people are very devout, for it is common to see a madonna in different shops with a lamp burning before the image until evening.

There are many charitable establishments here, including hospitals, schools, and colleges. The Great Hospital, which receives patients of both sexes, is a spacious building, with a court of above 300 feet square, lined with a double portico, supported above and below by columns of different orders. The whole can accommodate 1500 patients, or even 2000 on extraordinary occasions. Great operations are performed during summer, under a portico open to the street, where the groans of the sufferer are audible to the passengers, and his person would be exposed to their view, were it not concealed by the surrounding crowd of students. A smaller hospital, containing only 40 beds, is better managed: and there is likewise a military hospital. The Lazaretto, environed by a ditch or canal, is a vast quadrangular edifice, 1250 feet in length, and 1200 in breadth, all of brick, containing 304 rooms, with fire-places. A chapel is so contrived in the centre of its court, that divine service may be seen by the sick from their beds.

The college of *Brera*, once belonging to the Jesuits, was more lately denominated the *Palace of the Sciences* by the French, because physic, sculpture, architecture, painting, and engraving, are taught in it. This edifice has a square court, exhibiting two stories, the one supported by Doric, the other by Ionic columns, which are connected by a grand staircase. Here are a good collection of machines, for illustrating the physical department, an observatory, a library, together with a cabinet of 12,000 medals, and a botanic garden.

There are several libraries in Milan, of which the chief is that of the college of Brera, and the next, the Ambrosian, founded by a cardinal of the Borromean family, a nephew of the archbishop above mentioned, in 1609. Its contents exceed 40,000 printed volumes, and 15,000 manuscripts, the former ar-

* See Civil Architecture, and Plate CLXV.

ranged in a spacious gallery, the latter in a separate apartment. Though open daily, and considered a public establishment, this library is always under the direction of the head of the family as its property. Many valuable writings were preserved in it, such as a translation of the works of Josephus, executed 1200 years ago on the bark of a tree; Virgil's Works, with Notes by Petrarch; those of Gregory of Nazianzen; twelve volumes of mathematical, mechanical, and architectural drawings, by Leonardi de Vinci: But the most valuable portion was carried to Paris along with the rest of the plunder of Italy, and it is yet unexplained what has been restored. A library belonging to the Monastery of St. Ambrose is very rich in Latin manuscripts, besides a prodigious collection of charters and diplomas, some of which ascend to the eighth century, the whole being in excellent arrangement.

Literature has been successfully cultivated in Milan; besides Alciati, Beccaria, Carli, Verri, and other authors in history and political economy, this city has been embellished by the names of Pini, Landriani, Frisi, and Donna Maria Gaetana Agnesi, in the sciences. (See Agnesi.) Many valuable works also have issued from the press of Milan, among which may be named the *Historians of Italy*, in 25 folio volumes, by Muratori, published in the earlier part of last century, and the *Classical Italian authors on Political Economy*, in 48 octavo volumes, published in the earlier years of the present century.

The theatre della Scala, which is one of the largest in Italy, was built partly by subscription in 1776, on a magnificent plan. A great vestibule leads to the pit, and two fine staircases ascend to the boxes, of which there are five rows, besides a sixth, or gallery for attendants. The boxes are very spacious, and elegantly fitted up. It is said in a small work, published at Milan in 1817, that sometimes 40 horses and 600 persons are brought on the stage; and the theatre is so skilfully constructed, that the performance is quite audible in parts most distant from the performers. The hour of night is denoted from a transparency on the arch of the proscenium. Besides this, there are several other theatres, one erected after the same model, but smaller, and less decorated, for a French company; and another for the performance of amateurs. Some of the best operas extant have been composed for the theatre of Milan; and some eminent performers are generally engaged in gratifying the public taste for music.

A place of amusement, called the Arena, was lately constructed on the outskirts of the city, for the exhibition of great spectacles, and is capable of accommodating 30,000 persons. It consists of an oval amphitheatre, partly of grassy banks, partly of stone. The lower part of this Arena, which is 400 fathoms long, and 200 broad, may be entirely inundated by means of a small canal traversing it, and there nautical exhibitions, like the ancient naumachia, may be shewn; as was done to entertain Bonaparte.

Milan contains many fine houses: some distinguished by their architecture, others by their spacious apartments and elegant furniture. For the most part, they are decorated externally with lofty granite columns supporting large projecting cornices. That of the family of Litta has a façade with 32 pillars, besides four in the portico.

Much activity prevails at Milan, which is a place of considerable trade and manufacture. Workmanship in metals, embroidery in gold and silver, are executed in a superior style. There are extensive manufactures of silk in its different branches; of wool and goat's hair, glass and porcelain. Mosaic work, and that in pietra dura, is prosecuted on a larger scale, and in greater variety, than in any other part of Europe. Lately a piece of Mosaic, representing the last supper, with figures as large as life, was executed in colours after nature, on six pannels, extending 30 feet in length and 7 in height. It was commissioned by Bonaparte, at the price of 5000*l.* but the overthrow of his government interrupted the work, which has been completed very recently for another sovereign. The fertility of the neighbouring territory, in fruit, grain, and pasturage, affords abundant supplies, both for the consumption of this city, and for export.

Milan consists of 61 parishes, containing 120,000 or 130,000 souls. By some, the population is rated nearly one-fourth higher; and it is said to have been so in the course of the preceding century. In 1766, by actual enumeration, the inhabitants amounted to 111,450, exclusive of those occupying the religious houses, and a certain part of the suburbs. The state of society is considered very agreeable. Frankness and hospitality distinguish the citizens among strangers, and urbanity among themselves. They are devout and bigoted, it is said; but the austerities of monastic life, always calculated to degrade the more amiable sensiblities of mankind, are greatly softened here. A love of show prevails among the higher ranks to a much greater extent than consistent with their fortune, and luxury seems to be making the same inroads as in the other cities of Europe.

Milan, in respect to size, is the fourth city of Italy; its history ascends to a very ancient date; and none has been more exposed to the competition of contending powers; it is supposed to have been founded by the Gauls two centuries later than the building of Rome, whose early history, however, rests on the most uncertain data. In modern times, it has belonged to Spain, Austria, and France; but, although taken and re-taken several times since the French revolution, it was always without bloodshed. When the kingdom of Lombardy was formed by Bonaparte, he was crowned here with the iron crown of the ancient kings of Lombardy; and thenceforth Milan was considered the real capital of Italy. By his order, the fortifications were dismantled, and he built a triumphal arch of white marble, to record his own exploits. Longitude of the Observatory, 9° 11′ 45″ east, and Latitude 45° 28′ 2″ north.

MILBORNE Port, is a borough-town of England, in the county of Somerset. It is situated at the foot of a steep hill, on the river Ive, principally on both sides of the high-road from Yeovil to Shaftesbury. The church is a neat edifice, built in the form of a cross; but the houses, which are disposed in four streets, are, in general, irregularly built, and detached from one another. The guild-hall is an ancient building, with a door-case, partly of Saxon, and partly of Norman architecture. It has considerable manufactures of dowlas, ticking, linsey, stockings, and shoes, which employ a number of hands. The population of the borough and parish, in 1811, was 224 inhabited houses, 132 families, and 1000 inhabitants. See Collinson's *History and Antiquities of Somersetshire*, vol. ii.; and The *Beauties of England and Wales*, vol. xiii. p. 524.

MILDEW. See AGRICULTURE.

MILFORD, or MILFORD-HAVEN, is the name of a sea-port town of South Wales, in the county of Pembroke, beautifully situated on a small promontory, the sides of which descend gently to the sea. The principal harbour extends to the south, and resembles a large lake. It has sixteen creeks, five bays, and 13 roads. It is regarded as the safest and most commodious in the world, and is capable of holding a thousand sail in perfect security. The town consists of three streets, extending from east to west. The church, which is a handsome building, consisting of a nave, chancel, and two side aisles, stands at the end of the lower row of houses. The old chapel of St. Catharine stands at a short distance to the east, and has been converted into a powder magazine. The market-house and custom-house are neat buildings. Two batteries, each mounting seven guns, have also been erected, for the defence of the town.

The principal trade of Milford consists in its South-Sea whale-fishery, which has been successfully prosecuted by a colony of Quakers, from the island of Nantucket. There is likewise some trade in wood and naval stores. A dock-yard was formed at the suggestion of Lord Spencer, and several large ships of war were built in it, and others repaired. Longitude of Milford steeple 5° 20′ 13″ west, and Latitude 51° 42′ 43″ north. See Corbet's *Geographical Dictionary of Wales*; Fenton's *Historical Tour through Pembrokeshire*; and the *Beauties of England and Wales*. Vol. xviii. p. 755.

MILITARY TACTICS.

THE art of war may be considered as coeval with the history of the world. The evil passions inherent in human nature,—hatred, envy, covetousness, ambition, and revenge, first gave birth to this destructive art, which, however rude in its commencement, has, in the course of time, gradually advanced to the importance and dignity of a science.

At first, the art was probably limited to the display of individual strength, courage, and address, in wrestling, boxing, and the employment of the most simple offensive arms. But as civilization advanced, and societies became more extensive, larger bodies of men were employed in warlike enterprises; the advantages of a certain degree of order and combination soon became obvious; and experience gradually suggested the use of various instruments, to render more efficient the natural force and activity of the limbs in close conflict, or to annoy the enemy from a distance. The art of war now attained to that state nearly, in which it is still found among the Asiatic tribes, consisting of a mass of rude principles, which could scarcely yet be honoured with the name of science. Meanwhile, there arose men of great talents and ambition, who, being occupied during the greater part of their lives in warlike enterprizes, brought the art to a greater state of perfection, and made use of it as the instrument of their glory and aggrandisement.

Guibert distinguishes five or six great epochs, in which important changes were effected in the principles of military tactics. It was among the Asiatic nations, and particularly among the Persians, that the art appears to have first assumed a systematic form. The Egyptians, attached to the peaceful sciences, made little progress in the military art; and, excepting under Sesostris, they never were a conquering people. After the death of Cyrus, the military art passed to the Greeks; and this brave and ingenious people reduced it to systematic principles, and brought it to a great degree of perfection. Alexander extended it still farther; and, in his time, the Macedonian phalanx was esteemed the most perfect order of battle which had ever been invented by military science.

The principal weapon of the Greeks was the spear or pike, which they used with great skill and dexterity. When in order of battle, the Greeks and Macedonians were frequently drawn up on a depth of sixteen, and even thirty-two men, placed in files, one behind another. This deep and dense order, while it could be perfectly preserved, enabled them not only to resist the most vigorous attacks of their enemies, but to penetrate and lay open whatever opposed them.

The Romans adopted other arms, and a different mode of fighting. Their favourite weapon was a short cut-and-thrust sword, easily manageable in the hand, and admirably adapted to give effect to the courage and activity of their soldiers in close conflict. They rejected the dense order of the Greeks, as incompatible with the use of that weapon, and drew up in long full lines of three men in depth, much the same as in our present European armies; with this difference, that the men were arranged, not in files one behind another, as is now done, but each man in the succeeding rank was placed diagonally, so as to cover the interval between the two men in the rank before them. Besides, the Roman soldier, in order to have the full play of his short sword and buckler, required a great deal more room in all directions than either the Macedonian or modern European soldier. Such were the arms and discipline of the Romans, which, seconded by their courage and skill, enabled them to triumph over the Grecian phalanx, and to maintain for ages the sovereignty of the world.

During the decline of the Roman empire, the science of military tactics was almost entirely neglected, and the empire itself gradually became a prey to those numerous swarms of barbarians whom the hopes of plunder invited to its conquest. For a long period the military history of Europe only presents to our view armies with little discipline and less science; battles gained by numbers, by valour, or by chance; and conquests equally rapid and destructive. Even the invention of gunpowder, although it necessarily occasioned considerable changes in the mode of fighting, does not appear to have immediately led to any very important improvements in tactics.

Maurice, Prince of Orange-Nassau, and Gustavus Adolphus of Sweden, are justly considered as the fathers of modern military science. Both were men of learning and research, as well as of genius; and both carefully studied the art of war in the writings of the Greeks and Romans. Their admiration of the ancients, indeed, was perhaps carried to excess, and led them to the servile adoption of principles, which were no longer suited to the times, or to the arms then in use. But there is no doubt, that we are chiefly indebted to them for the revival of military tactics and discipline. They kept up the prejudice in favour of the dense order of battle, and the use of the pike; but, on the other hand, they shewed the advantages of the oblique order, and invented the present grand basis of military operations, —a triangle resting on a chain of magazines; besides introducing many other minor improvements in the discipline and disposition of the troops.

After the death of Gustavus, Bernhard, Duke of Weimar, Horn, Banner, Torstenshon, Turenne, Montecuculi, and others, fought with success according to the principles of their master; and the art of war continued in certain respects to improve. This, as Guibert observes, was the age of great generals, commanding small armies, and doing great things. Some circumstances, however, still concurred to retard the progress of military science: among which may be reckoned the servile adherence to the ancient tactics, the prejudice in favour of the dense order, and the continued use of the pike, which even the celebrated Montecuculi used to call the queen of arms.

Towards the end of the seventeenth, and the beginning of the eighteenth century, great improvements were made in certain branches of military science, while others were almost entirely neglected. Coehorn and Vauban brought the art of attacking fortified places to a state of perfection wholly unknown to the ancients. The art of defence, however, was far from making equal progress. In the mean time, armies became much more numerous; and the quantity of artillery was prodigiously increased. Louis XIV. gave the example, which was soon imitated by the rest of Europe. Armies so numerous, and with such immense trains, were less easily supplied and put in motion; and the duties of a general were more complicated and more difficult. Condé, Luxembourg, Marlborough, Eugene, and a few other generals of transcendent talents, were able to move these masses; but men of inferior genius sunk under the weight.

Sufficient justice, we think, has never been done to the talents of Marlborough, unquestionably the first commander of his age. The consummate skill which he displayed in the conduct of large armies; the correctness of his *coup-d'œil* in chusing positions, and discovering the weak points of the enemy; his quickness in detecting the faults of his antagonists, and the rapidity with which he took advantage of them; above all, the uniform and brilliant success which attended all his enterprizes, attest the pre-eminence of his military genius. But neither Marlborough, nor any of the other generals of his time, can be considered as inventors in the art of war. They may have made a more or less skilful use of the princples already established; but none of them appear to have introduced any thing new, either in the organization of armies, or in military tactics.

At this period a great schism prevailed in the opinions of military men with respect to the changes necessary to be introduced, in consequence of the use of fire arms. All Europe was divided on the question, whether the dense order of the ancients ought to be rejected, as exposing the troops too much to the destructive effects of artillery? This question was discussed in various writings, without producing any settled conviction. The Chevalier Folard proposed his columns as the fundamental and almost exclusive order for infantry; and his opinion gained many partizans. The army, in short, was on the point of resuming the pike, and forming the phalanx. The war of the Succession, and that of 1733, were conducted upon these unsettled principles; the battalions forming on a depth of from four to six, and the officers of the old school demanding the resumption of the pike, which Vauban had brought into disuse.

We now approach that period, however, when the science of military tactics assumed a more decided and scientific form. Under Charles XII. the Swedish soldiers were still animated by the same spirit which they had manifested under Gustavus. His infantry, hardy and indefatigable, in a state of discipline as perfect as the Roman legions in their best times, and commanded by excellent generals, who possessed a considerable knowledge of modern manœuvres, performed actions which astonished Europe. But Charles was too limited in respect of his means; and his carrer, however brilliant, was too short, to enable us to form a perfect estimate of what he might have been capable of accomplishing under different circumstances; and he has even left us in doubt regarding the extent of his knowledge, and the powers of his genius.

Meanwhile, a new kingdom was formed on the banks of the Oder and the Spree, whose sovereigns having neither commerce nor maritime power, devoted themselves to the creation of a formidable military force, which should enable them to assume an imposing attitude among the European powers. Frederick II. completed the plan which had been chalked out by his predecessors. He not only doubled the number of his troops, but improved their discipline, and invented a system of tactics almost entirely new. He was perfectly well acquainted with the state of the military art among the ancients, and employed his genius in discovering and bringing to perfection such manœuvres as were best adapted to modern warefare. His efforts were amply rewarded by his first successes in the field. But even during peace these efforts were not relaxed. He formed camps at Spandau and at Magdeburgh; exercised his troops continually in the most scientific and effective movements; rectified whatever experience shewed to be defective; and introduced an incredible degree of decision and celerity in the execution of all the necessary manœuvres.

During the seven years' war the efficacy of discipline and tactics, under the conduct of genius, was fully evinced. In the war of manœuvres, as may easily be conceived, the king of Prussia was eminently successful. He was frequently defeated in pitched battles; but he seemed to rise, like Atræus from the earth, with fresh vigour and renewed courage; and it was remarked that he never was more formidable than when his enemies believed him to have been effectually crushed. Such was the state of discipline to which he brought the Prussian troops, that they frequently made forced marches, lost a battle, left behind them the greater part of their cannon, and took up a position at the distance of a couple of leagues from the field where they had been defeated.

But the merit of the king of Prussia does not rest entirely on the improved discipline of his troops; his genius was equally occupied with the scientific principles of military movements; and the Prussian tactics have accordingly been considered as forming an æra in military history. Frederick shewed that the movements of an army of 100,000 men may be reduced to rules as simple as those of an army of 10,000; and that having once discovered the spring which regulates the movements of a single battalion, it is only necessary to combine a number of these springs, and to handle them with skill. He has been considered as the real inventor of light, or flying artillery; but his inventive genius chiefly distinguished itself by his improvement of the oblique or angular order of battle, the principles of which he studied profoundly, and carefully explained its mechanism to his generals.

From the time of Frederick, it does not appear to us that any very important improvements have been made in military tactics. During the late wars, indeed, the French adopted a mode of fighting in some respects new; but this was a necessary consequence of the character of their troops, and their imperfect state of discipline. Instead of lines, that could with difficulty be preserved in the face of an enemy superior in discipline to themselves, they formed close columns. Their battles also were reduced to attacks on certain points, and sometimes on one only. By brigades constantly succeeding each other, and fresh troops supplying the place of those who had been driven back, they generally succeeded ultimately in forcing the point attacked. In their movements, whatever was lost in regularity and precision, was amply compensated by increased velocity. To the rapidity, indeed, with which their movements were executed, they were indebted for much of their success. They also derived great advantage from the employment of numerous bodies of light troops of various descriptions, and the improved and extended use of flying artillery. In their battles, too, they generally kept a large body of reserve, composed of the best troops, and commanded by an able general, which, on more than one occasion, was the means of recovering a battle which was considered as lost.

The French likewise introduced considerable changes in the subordinate arrangements of the army during a campaign. Their wants were supplied by requisition; and when they entered a country they had little or no baggage. By abandoning the old system of forming depots and magazines, they certainly exposed their troops to famine, want, and disorder; but, with all these inconveniences, they appear to have reaped very important advantages from this mode of supplying their armies. Their movements could not be anticipated from the magazines they had formed, and the position of their depots; and their route was not liable to be retarded by the attention which it would have been necessary to pay to these objects. The inroads of the French armies, therefore, were unexpected, and their progress rapid. They calculated only upon success; and they generally obtained it by the celerity of their movements, and the boldness and enterprise of their plans. At the same time it must be observed, that as they generally put every thing to hazard, and neglected or despised those precautions which frequently mitigate the consequences of bad success, their defeats were almost always attended with the most disastrous results. Excepting under Moreau, and one or two other generals, who were attached to the principles of the old school, we seldom find a French army making a skilful and scientific retreat.

The apparent want of discipline among the French troops, their frequent abandonment of the ordinary principles of tactics, and their extraordinary successes, have induced many superficial writers to talk lightly of the whole system of tactical rules and regulations, which science has suggested, and experience improved. We suspect, however, that they have not paid due attention to the real state of the circumstances. The truth is, that, excepting at the earliest period of the revolutionary war, the French troops never wanted discipline, but, on the contrary, they possessed that requisite in a very high degree. They had also the advantage of a great number of skilful officers, educated in the very best school, that of actual service. In the dressing of their troops, as well as in the execution of various manœuvres, they threw aside every thing that was useles or unimportant, and retained only that which was essential, frequently simplifying the principles, and accommodating them to the genius of the nation, and the character of the troops.

The German system of tactics, as established by Frederick of Prussia, although undoubtedly, in some particulars susceptible of modification according to circumstances, will still be found to exhibit the fundamental principles of military science. In this article, therefore, we shall endeavour to present our readers with a compendious view of those principles, following chiefly the order adopted by Mauvillon, in the third part of his *Introduction to the Military Sciences*. At the end of the article we shall also subjoin a list of writers, whose works we have occasionally consulted, and to whom we would refer such of our readers as are desirous of acquiring more minute information on the subject.

Writers on military tactics have generally divided the subject into two parts. The first, or *Tactics*, strictly so called, relates to the composition and discipline of an army, and to those dispositions which are requisite for its security and regular supply, and to render it efficient for service, without an immediate reference to the actual presence of an enemy. Under this head are also comprehended practical tactics, or the rules to be observed in the conduct of detachments, and also castrametation, or the art of encamping on the field. The second explains the general principles upon which the operations of an army are conducted against an enemy in the field; or what is technically called *Strategics*. This division of the subject has been objected to by some; but for the sake of method, we have resolved to adhere to it, although we are willing to admit that the limits of each division have not been very precisely defined.

Part I. TACTICS.

Sect. I. *Of the Composition of an Army.*

An army consists of an indefinite number of armed men, assembled together and placed under a certain state of discipline, for the purpose of carrying on war. It may be divided into Infantry, Cavalry, Artillery, and Engineers.

The infantry consists of regular infantry of the line, and light infantry. The infantry of the line was formerly divided into grenadiers, fusiliers, and musquetiers. This division was founded upon certain differences in their arms and modes of fighting, and is now no longer in use. The grenadiers, however, are still retained in all services; they are selected for their size and strength, and are principally employed in enterprises requiring great force and courage.

The arms of the infantry consist of the musket and bayonet; formerly they had also side-arms, but these were found to be more ornamental than useful. The proper length and construction of the musket have not hitherto, perhaps, been precisely ascertained; the practice of different nations varies in this respect; but the perfection of this weapon consists in the largeness of its calibre, its durability, its projectile force, and the correctness with which it carries the bullet. The utility of the musket, as a warlike weapon, has been greatly increased by the addition of the bayonet, which enables troops thus armed to come to close combat. The use of the bayonet was first introduced by the French, about the end of the 17th century, and it has since become general.

To enable the soldiers to use their arms, and at the same time, to render the enemy's artillery less destructive, the infantry is placed three deep, so that they can fire at once and behind each other. Each man occupies a space of about two feet in rank and file, a sufficient interval being left between the files to admit of the freedom of individual motion.

As in the case of individuals, all kinds of troops can attack and defend themselves only in front. Every number and description of troops, therefore, must be placed so as to attack in front, and to be liable to be attacked in front only.

Their arms afford the infantry a twofold mode of fighting. They either endeavour to throw the enemy into confusion by their fire, or they march rapidly upon him, charging with the bayonet, in order to break his line. As the firing generally carries off so many of the troops, that a part of the line is either entirely broken, or much weakened, before the armies approach near enough to each other, a charge, or at least an actual combat with the bayonet, seldom takes place, except in extraordinary or accidental circumstances. The French boasted much of their success with the bayonet in their late battles; but the way, it is believed, was always pretty well cleared by their numerous artillery previous to the charge. In the hands of British soldiers, the bayonet has always proved a most efficient and decisive weapon, as they have always, indeed, been distinguished for their courage and firmness in personal conflict.

In order to facilitate the government and movements of an army, it is divided into small bodies of men, called battalions, consisting of from five to seven hundred men. Each battalion is provided with two field-pieces; and when several battalions are placed together, they preserve as much distance between them as is necessary for the management of the field-pieces, and to enable persons to ride through conveniently. With cannon attached, the interval between batallions is twelve paces; without cannon, it may be six paces. A greater interval is always a consequence of necessity. In large armies, several battalions are formed into brigades, several brigades into divisions, and these divisions into larger bodies, called *corps d'armée*, each placed under the immediate command of officers of a certain rank.

Infantry are capable of acting upon every species of ground, and are therefore the most essential constituent of an army. It is thought dangerous, however, to expose infantry to the attacks of cavalry upon a plain, where the latter are always most efficient, and the former are liable to be broken, especially if they should attempt to put themselves in motion. But recent results seem to have demonstrated, that a well disciplined infantry, properly disposed, are, in such a case, not only capable of opposing a successful resistance to cavalry, but even of becoming the assailants in their turn. In all broken and uneven ground, such as hills, woods, villages, behind hedges and fences of every description, rivers, morasses, and all kinds of entrenchments, infantry can be most effectually employed, both for attack and defence.

The following are general rules for the disposition of infantry upon different kinds of ground.

1. On hills, infantry must be posted so as to command the whole declivity; and therefore they must not always be placed on the very highest ridge, or summit, much less behind it, if the object be to oppose the ascent of the enemy.

2. When a wood is to be occupied by infantry, they should be placed on the edge of it, so as to be concealed by the trees, while, at the same time, they are enabled to fire upon an approaching enemy. A combat with infantry of the line can seldom take place within a wood, unless where an attack is made upon a detachment posted there to obstruct an enemy's passage, or in light open places.

3. In villages, the infantry, when numerous, occupy the hedges and fences of the gardens, or orchards, outside, so as to command the fields beyond them. When attacked in this situation, they retire gradually from hedge to hedge, and occupy the gardens themselves, with the houses and streets within their line. The same rule applies to farms and fields that are subdivided by hedges or other fences. As the regular infantry always fight in a body, and in line, care must always be taken, in occupying hedges, villages, &c. to preserve a communication in every direction, in order that one part may support the other, and that the whole may always form one connected line, impenetrable to the attacks of the enemy.

4. Infantry are posted behind rivers, morasses, ravines, &c. in order to prevent, by their fire, the passage of the enemy. For this purpose, it is by no means necessary to occupy the whole length of the bank, but only to be posted so as to keep all those places where the enemy can effect a passage, at the distance of a short gun-shot, under their fire, and that fire, if possible, a cross one.

The regular infantry lie in the field under tents, which are carried on baggage-waggons, or on horseback. Every battalion carries along with it two field-pieces, and the necessary ammunition. As in the course of an active campaign they are not quartered in towns and villages, they must also carry along with them several other necessary articles, which swell their baggage to such a considerable bulk, as frequently proves an impediment on service.

Of light infantry, there are a great many different kinds, with an almost endless variety of designations; such as riflemen, sharp shooters, or tiralleurs, chasseurs, voltigeurs, &c. In some services, the troops of certain nations are especially destined to the duties of light infantry. Light infantry differ from regular infantry, principally in their arms, equipments, and mode of fighting. In their arms there is less difference now than formerly, only that those destined to act as riflemen are armed with rifles, instead of common fire-locks. Their baggage is less bulky than that of the regular infantry, and they have no field-pieces attached to their battalions. Their mode of fighting is less regular than that of the infantry of the line, and requires more individual skill and intelligence. In what is called the *petite guerre*, especially in mountainous countries, this description of troops is most eminently useful. In the late war, the French appear to have brought the light infantry service (for which the character of the people seems peculiarly adapted.) to great perfection. It frequently happened that their light troops were enabled, by the vivacity of their movements, to harass, exhaust, and ultimately subdue more numerous bodies of regular infantry.

The cavalry are composed of heavy and light horse. The former may be divided into cuirassiers and dragoons. The cuirassiers only have defensive armour, viz. a cuirass or iron mail, which protects the breast and back. In the British, and some other services, there are no cuirassiers. Indeed, it has been found, that the cuirass is of little use, and, on the contrary, proves a great impediment to the free motion of the rider. The dragoons are armed with a sword, a carabine, and a pair of pistols. The cavalry are placed in two ranks, although the first only can act immediately against the enemy. The second line, however, tends to give more firmness to the whole body, and can supply the places of those who fall in front. Their manner of fighting consists in endeavouring to throw the enemy into disorder by the *impetus* of their attack, and then to cut them down with their swords. Every thing therefore depends upon their preserving order with the greatest possible celerity of motion. The cavalry, as well as the infantry, are placed in small bodies, called squadrons, at certain small intervals from each other. A squadron generally contains from 120 to 160 horse.

Cavalry, and especially heavy horse, can only be employed in a champaign country, and on firm ground; but there they are capable of acting not only against cavalry, but also against infantry, and even in the attack of batteries. The celerity with which they are enabled to perform their manœuvres, renders them peculiarly well calculated for all decisive movements, such as cutting off, or turning the enemy, falling unexpectedly on his flanks or rear, &c.

Dragoons were originally a mounted infantry, who were employed in all enterprises requiring speed. They sat on horse-back, but frequently fought on foot. Even to this day, they are still armed and exercised with a view to being employed as infantry in a case of necessity; but they are almost never used as such, and are therefore to be considered solely as cavalry. In default of light horse, their duties must often be performed by the heavy dragoons.

The cavalry carry their tents on horse-back along with them. The horses stand in the field, in the open air, and are picketed in lines before the tents in which the riders lie. As the cavalry have no cannon, and carry almost every thing they want upon their horses; in which care must be taken not to overload them; they are, on this account, not liable to have their motions impeded by their baggage. They are more frequently, however, embarrassed by the care of providing for the maintenance of their horses. They must provide forage for themselves, taking it either from the fields in summer, or from the magazines or villages in spring and autumn. The former is called green, the latter dry forage.

The light cavalry have smaller horses, lighter arms and accoutrements, and less baggage than the heavy horse. In foreign services, particularly the German, the light horse are generally called hussars, and are clothed in a manner corresponding to the name. In the British service also, there are several regiments of hussars. The mode of fighting peculiar to the light cavalry, consists generally in constant skirmishing, either advancing or retreating. But when well disciplined and efficient, they should be able, when necessary, to charge in close order, and to execute all the manœuvres of the heavy cavalry.

The following are some general rules for the service of light troops, whether infantry or cavalry.

1. They should keep as near the enemy as possible, in order to ascertain the intention of all his movements; and, 2. They should follow him in all his movements. 3. They should constantly engage in enterprizes against him, by carrying and occupying posts, intercepting convoys, destroying magazines, harassing the enemy on all sides, and carrying off stragglers, &c. 4. They should pursue the enemy when beaten, and hinder his pursuit when victorious. 5. They should bring contributions and supplies from a distance; and, 6. They should endeavour to conceal the movements of their own army. For this purpose, they form a chain of posts in front, and on the flanks of the army, which must support each other, and be able to retire upon their main body. The different species of troops, in these operations, must be placed so as to enable them to act most advantageously: The cavalry in plains, and accessible places; the infantry on irregular ground, in tenable places, and behind entrenchments.

The artillery consists of cannoneers, bombardiers, sappers, miners, and pontooners. The cannoneers and bombardiers serve the cannon, and a certain number of them are attached to every piece. As they do not fight like other troops, they are, in general, only provided with side arms; sometimes, however they carry other weapons, to be used on occasions. Sappers and miners are employed only in sieges, and are armed with pistols and daggers, which the latter use under ground. The sappers are seldom required to use arms of any kind, which with them, therefore, are more ornamental than useful. Their duties consist more in exposing themselves than in giving personal annoyance to others. The same applies to the pontooners, whose duty it is to attend the pontoons, (a kind of small copper boats,) which are carried in waggons behind the army, in order to throw bridges over rivers, and they must therefore possess all the skill requisite for this employment.

The horse-artillery, or flying-artillery, are of recent introduction, and were first employed, with great effect, by the French, in the late war. They had no field-pieces attached to their battalions, but this deficiency was amply compensated by their numerous horse-artillery. The best and most skilful men are selected for this service, and being mounted, they are enabled to act with great expedition, and to move rapidly to any part of the field. The horse-artillery are divided into troops, as the field-artillery are into companics. The men are armed with large sabres and a pair of pistols; some of them also with rifles.

The engineers are particularly useful in conducting all the scientific operations of war. They are generally divided into fortress-engineers and field-engineers. The former are employed in the construction of fortifications, and in conducting the attack and defence of fortified places. The duties of the latter consist in surveying, reconnoitering, or drawing plans of positions, directing the movements of an army during a march, choosing proper ground for encampments, constructing field fortifications and entrenchments, and pointing out the proper mode of attacking the fortified positions of an enemy. See FORTIFICATION.

Besides the various descriptions of troops already enumerated, almost every army is attended by a number of guides and pioneers The business of the former is to point out the best roads for an army on march; that of the latter to render the roads passable, by removing obstructions, &c. The sappers and miners are employed in digging out ditches, and constructing other works, in order to facilitate the approach to a fortress, and in excavating the earth, and undermining the ground, for the purpose of blowing up some part by the explosion of gunpowder.

The staff of an army consists of all those officers, to whom is confided the care of commanding, directing, and providing for the troops; such as the general commanding, the quartermaster-general, adjutant-general, commissary-general, provost marshal, physician and chaplain to the forces, &c. with their respective aides-de-camp, deputies, assistants, &c.

The fatigues and dangers of war render it necessary to establish lazarettos and hospitals, with a requisite number of physicians and surgeons, for the care of the sick and wounded. Such of the sick as are dangerously ill, and require a tedious cure, are placed in the lazarettos, which are generally situated in towns and villages at some distance from the army. Others, whose cases are more slight, are placed in the flying-hospitals, which follow the army, and require an hospital-train.

Spies are also necessarily employed by an army; that is, persons who, for money, endeavour to ascertain and communicate the circumstances and intentions of the enemy. These may be people belonging to the country occupied by the enemy; persons who go in disguise to procure information; or persons from among the enemy themselves, who are bribed to discover all that they know. Spies must always be well paid, especially in the last mentioned case, and their information should be received with great caution, and compared with that obtained from other quarters. Spies giving false information, must be severely punished, unless, perhaps, we may be able to turn this circumstance to our own advantage.

SECT. II. *Of Castrametation.*

The art of castrametation, or the choice of ground for a camp, and the disposition of the various descriptions of troops in it, was formerly a matter of infinite consequence in war. Of late, however, it has become of much less importance, as troops, at present, seldom carry tents along with them, but are placed in cantonments when intended to be kept in readiness for the field, or when obliged to lie in the field for a short period, they have recourse to the *bivouac*.* But although regular encampments are now much less frequent than formerly, it is necessary that we should explain the principles of castrametation, because these are applicable, not only to the choice of situations for camps, but also for positions in general, and will be found of especial use in determining the order of battle for an army acting chiefly on the defensive.

There are two general and fundamental rules for the choice of a camp. In the first place, the situation of the ground should be such that an attacking army can derive no benefit from it; and secondly, such disposition must be made as to secure the camp from being surprized.

In order that the enemy may derive no advantage, but the reverse, from an attack on the army encamped, the following special rules must be attended to. 1. The ground for the camp must neither be too large nor too small. 2. The enemy must not have it in his power to approach either on the flanks or the rear. 3. He must not have the power of making a sudden attack on the front without meeting with immediate resistance. 4. The approach to the front must be difficult, and on his advance, the enemy must, at every point, be constantly kept under a stronger fire of artillery than he can oppose. The more difficult the approach, the stronger is the camp; and when difficult of access at every point, it may be said to be unattackable. 5. Every part of the army encamped must be able to come to the assistance of the rest. 6. The outlets from the camp, on every side, must be easy.

With respect to the size of the camp, the following observations may suffice. 1. Its length must be equal to the space occupied by a battalion and a squadron under arms. In determining the length of the camp, however, according to this method, provision must be made for the intervals formerly mentioned, which, if necessary, when the whole number of troops are not there that the space would require, must be reckoned larger; but at the same time, never larger than the front of a battalion and squadron, which is called the half line. 2. An army is never encamped in a single line, but in two, at the least, with some picked troops in reserve behind the second line. 3. In order to determine immediately in what situation of the line each battalion should be placed, an order of battle for the whole army is formed at the commencement of every campaign. The regiments are thus placed according to their rank or number; the first on the right, the second on the left wing of the first line, the third on the right, the fourth on the left wing of the second line, &c. When a battalion or squadron is detached from the line, the others close, and occupy its place. It is always easy, therefore, to determine the necessary length of the camp, according to the number of battalions and squadrons in the first line. 4 To determine the depth, it must be observed, that each line requires three hundred paces for the depth of its encampment, which is also the distance assigned to them when drawn up in order of battle, that the second line may not suffer from the fire on the first.

The second rule we have laid down requires that the

* Troops are said to bivouac, when they lie out without tents or regular covering from the weather. As troops now carry no tents, this sometimes becomes a matter of necessity.

flanks should be covered. The flanks are said to be covered, when the enemy can neither attack them directly, nor march round that which covers them, without leaving full time for taking measures to frustrate his intentions. Hence we must determine the fitness of the objects upon which the wings rest. The wings may rest on the sea. In this case we must ascertain the depth of the water, and, if necessary, protect the wing by a staccado, or some such means, as far as the water is so shallow as to allow a person to wade through it. Regard must also be had to the changes produced by the ebb and flood tides; and care must be taken to prevent the army from being annoyed by the ships or boats of the enemy. 2. On rivers, which afford an excellent support to the flanks of an army, when there are few or no natural or artificial means of passage; and the few are sufficiently protected from the enemy. 8. On lakes or ponds. The extent of the circuit which the enemy must make to get round must determine the fitness of these objects for covering the flanks. 4. Swamps or morasses also afford a good covering, provided we are certain that they are impassable. 5. The same may be said of mountains and ravines, when very precipitous; but when easily ascended, they ought to be fortified. Ravines form a good covering when the banks towards the enemy are lower than those occupied by the army encamped. They should, however, be fortified and occupied, in order to prevent a surprise. 6. Woods afford no good covering, even when ambuscades are placed in them, because the enemy may approach unseen, and easily overpower the ambuscade. 7. Villages, when well situated and tenable, are a good covering for the flanks; but they must be well fortified, and occupied by a sufficient number of troops to prevent an attack on the part of the enemy, because the safety of the army depends on their being maintained.

In following out the third rule, it is necessary, that, to the distance of a cannon shot in front, there should be no wood, village, hill, hedge, or other object, to obstruct our view of the enemy's movements;—no ravine, or hollow way, which could lead him unseen near to our front. Every thing must be quite clear before the front, and the enemy must be exposed to our fire, while all his movements are so well seen that we may always be prepared against any enterprise on his part. Such objects, therefore, as above described, when they do exist, must either be destroyed, or occupied, and fortified.

The fourth rule has much in common with the first, because whatever covers the flank also protects the front, the flank being always secured against every attack; while, when an attack is expected in front, it is sufficient that it be rendered difficult. An army is never encamped with the front to the sea, unless to prevent a landing; and in that case we must endeavour to concentrate the fire upon those points, where the nature of the coast is favourable for a descent. Ponds, lakes, and inundations, so far as they cover the front, present such obstructions as render it unattackable. A river is also a great obstruction, the greater in proportion to its breadth and depth, the paucity of fords or bridges, and the more those situations at which the enemy can cross are exposed to our fire. A perfect morass renders the front unattackable, and it also affords a good covering when it cannot be passed without difficulty. Woods in front are of no use, but rather a disadvantage, because they conceal the motions of the enemy. Glens, ravines, hollow-ways, &c. are a great protection to the front, when they run parallel to it; but when they run at angles into the camp, they must be occupied along their length. Villages, when tenable, and lying near the front, may be of great service; but the directions formerly given with respect to those objects, must be attended to. Single houses, castles, and other buildings, lying before the front, must be occupied so as to enable us to maintain a fire upon all that comes within a gun-shot of the troops.

The fourth rule requires that no river, morass, ravine, or considerable hollow-way, or impassable wood, should run through the army, much less between the two lines. When such objects occur, sufficient and permanent communications must be made over them, according to circumstances.

The sixth rule requires that regard be had to the object we have in view. The rule is, that as soon as an army enters the camp, roads must be made on all sides, to enable the troops to march out conveniently. But in all circumstances this rule cannot be observed. For a strong camp, affording at the same time facilities for marching out, will not easily be met with. If the object, therefore, be to have the facility of marching forwards on the enemy, less attention is paid to the strength of the camp. If, on the other hand, it be our intention to await the attack of the enemy, less regard is paid to the facility of marching out in front, provided only that the march towards both sides, and especially towards the rear, be open and convenient.

Finally, it is obvious, that if there be heights in the neighbourhood of the ground where we wish to encamp, the camp should be placed on them, and not in the low grounds.

In order to secure a camp from surprise, it is necessary to establish posts and field-guards. These posts must be placed in such manner, and at such distance, that the army, in whatsoever order it may happen to be, may be enabled to prepare for defence before the enemy can make their attack. They must therefore form a chain round the army, each supporting the other, so that nothing can pass through unobserved. They consist of infantry or cavalry, with light-troops, or troops of the line. On plains, and where objects can be seen at a considerable distance, cavalry are posted; but in broken ground, infantry are required. A post of light horse must be supported by one of heavy cavalry behind; which last is also supported by light or regular infantry. In woods, behind hedges, &c. light infantry are commonly placed; the regular infantry in villages, houses, and, last of all, behind entrenchments. Every large post places a smaller one at some distance, but in such a manner as not to be liable to be cut off. The sentries of all these posts, two of which always stand together, must be able to see and hear each other. The cavalry posts are frequently placed at greater distances during the day, and drawn closer at night. The field-guards of the cavalry are placed, not for fighting, but for watching; as soon, therefore, as a superior enemy approaches them they must retire. The infantry posts, on the other hand, are almost always placed so as to be able to maintain their ground, and therefore they ought generally to defend themselves as long as they can, in order to give more time to the army to prepare for defence. As soon as any danger approaches a post, or is observed, notice must not only be communicated to the proper quarter, but when forced to retire, the circumstance must be made known to the next post.

Every camp should have a facility of obtaining supplies of water and wood, and the army should also be provided with the necessary forage for the first few days a least. Care must be taken, therefore, that the wells, ponds, springs, &c. be not wantonly spoiled, nor the forage in and around the camp.

The camp is generaly marked out before the arrival of the army. For this purpose, the regimental quarter-masters, with the pioneers of the regiments, and some detached troops, march in advance under the conduct of the quarter-master-general. The latter having chosen the situation for the camp, and determined, according to its length, how many paces should be allowed to each battalion or squadron, including the intervals; the aides-de-camp then assign to each regiment, according to the number of its battalions and squadrons, its proper place in the first, second, or third line; after which the regimental quarter-master sets off the ground for each, according to a scheme established in the war-order of every nation, by marking out the space of each tent, those of officers as well as of privates, with stakes. When the army enters the ground, every battalion marches to the front of its encampment in order of battle; the tents are erected, and the camp is complete.

The main principle in encampments is, that the army be placed in the same order as for battle; so that nothing more is necessary than to march out ready for fight. But as this principle is not always without exception, such measures must be taken as shall enable the army to make the necessary alterations in its order of battle, before an actual attack is made by the enemy. In order to be enabled to form more rapidly, and also to encamp in places where there is otherwise a want of depth, the king of Prussia, to whom the art of war is so much indebted in modern times, invented what has been called the method of encamping in order of battle; in which there are no passages for the companies, and the tents are placed close together in three rows for the three lines.

Sect. III. *Of Foraging.*

By foraging is meant bringing in food for the horses, when it is done by the cavalry themselves. Forage, as we have already observed, is either green or dry.

The first thing to be done in foraging is to ascertain, whether there be forage sufficient for the number of horses. In dry foraging, therefore, the magazines are inspected; in green foraging, an experienced officer is sent out to reconnoitre the quantity. This officer endeavours to ascertain how much corn and hay are contained within a certain space, which he measures by the square steps of his horse. He then prepares the field, and determines the number who can forage upon it, deducting one-third of the whole space for the spots upon which nothing grows. Practice renders this task very easy, and will enable one to determine the quantity, as well as the extent, tolerably well merely by the eye.

An order is then issued to the army, or to that part of it which is intended to forage, to have their foragers ready at a certain time and place, in order to forage for so many days. When there is to be a general foraging of the whole army, it must first be ascertained that nothing is to be apprehended from the enemy while the people are out. Otherwise the army forages by flanks, in order that they may be prepared to resist the attack of the enemy in the camp.

When foraging is carried on under cover of the army, nothing more is necessary than to see that order, temperance, and proper discipline are preserved, which, however, requires great attention. The foraging itself is conducted in the following manner: When the forage is green, a particular spot is assigned to every regiment, when their foragers dismount, and set to work by fours, while one holds the horses. The former reap the corn, bind it up, and place it on the horses. The rider then mounts, and when they are all ready, they march off by regiments; first the artillery, and other trains, then the infantry, and last of all the cavalry. In dry foraging, the villages are assigned to the regiments, from which they are to forage; and it is best when the peasants are made to bring together outside of the village what they are required to provide, which is then divided; by which means all excesses are more easily prevented.

If an attack upon the foraging party is apprehended, they must be covered by a force proportioned to that of the enemy, the extent of the foraging ground, and the means of defence which it affords. It should consist of heavy and light horse, with infantry. The relative proportion of these troops must be regulated according to the nature of the ground.

The covering force should march on the previous evening, and occupy the ground which is to be foraged. The chain is afterwards formed in the morning, while the foragers leave the camp. When the covering force marches at the same time, and at the head of the foragers, no man should be allowed to dismount and commence reaping until the chain is formed, and the order is given by the commanding officer.

As soon as the light troops, preceding the party, arrive upon the foraging ground, they carefully reconoitre the neighbourhood, to ascertain whether there be any places where the enemy might lie concealed, such as woods, villages, ravines, &c. Bridges, and other approaches, must be occupied by a strong party. Cavalry and infantry posts are then placed, who must form a chain of centries, who allow none to pass the limits for the purpose of foraging, and give immediate notice of every thing that approaches. These posts are established on the same principles as those round a camp; and this is called the chain, which, however, is only formed in this manner in green foraging. When the light troops and posts give notice that the enemy is no where to be seen, the commander orders the foragers to dismount. He places himself with his corps either at the most important station, or if more than one attack is apprehended, in such a situation, as will enable him conveniently to oppose the approaching enemy at every point. When the ground is of considerable extent, he divides his corps into divisions, which he places at the most dangerous points, so that they can always afford assistance to each other. But when he hears or perceives that an attack is made in any quarter, he ought not to hasten thither immediately with his whole corps, but must only engage so far as is necessary to oppose the force employed by the enemy; because the attack may be merely a feint. So long as the enemy does not appear in superior force, the commander must always endeavour to complete his foraging; but when the enemy is too strong, the foragers must be immediately sent to the rear without their forage; the chain must be drawn together, and the whole covering force make its retreat in the best possible order. In dry foraging, the dispositions are much the same, only that it is unnecessary to form any proper chain, as the forage is brought to one spot, and the men, therefore, are kept better together; and, indeed, the whole business is much less complicated.

Sect. IV. *Of Marches.*

As it is extremely difficult even for a single battalion to march to any distance straight forward in order of battle, this may be considered as impossible in the case of a whole army. It is necessary, therefore, to break the order of battle when setting out on a march, and to proceed in many files behind each other, with as small a front as convenience, or the nature of the road, may require. This is called marching in columns. If nothing were apprehended from the enemy, this might be performed without any great nicety. But as it is necessary to be prepared against every possible attack, and the enemy can be resisted successfully only when received in order of battle, there are certain rules which must be observed in marching. In the first place, the march must be so arranged, that the troops may be at any time placed in order of battle, in the most rapid manner possible. Secondly, all precautions must be taken, according to the description and number of the troops, and the nature of the ground, that the enemy may not be able to attack us before we are prepared to receive him in order of battle. According to these principles, the disposition to all marches, whether of large or small bodies of men, must be regulated.

The ultimate principle of these movements will be found in the evolutions of a single battalion, or what is called petty tactics. Petty tactics are nothing else than the art of placing a battalion or squadron, as rapidly as possible, in order of battle, out of every given position; and in that order which the nature of the ground, and the position of the enemy requires. A short review of these rules is a necessary preparation for the science of marches.

In most services, the battalion is divided into four divisions, and eight platoons; and this division is the foundation of all movements. When under arms, each man occupies a space of about two feet in rank and file, and the whole are placed in three ranks. But upon a march, it is impossible to proceed in such condensed order. Each man then requires the space of three feet on all sides. All step out with the same foot, and march regularly. The length of every step, from heel to heel, is generally thirty inches; and, in ordinary time, seventy-five of these steps are to be taken in one minute. In quick time, one hundred and eight such paces are taken in the minute; and in double quick time, one hundred and twenty. When the word is given to step out, the length of the step is about thirty-three inches. Experience proves that a quick march is incompatible with the preservation of order even for a short space. The quick marches, therefore, are only used in sight of the enemy, or when the troops are exercised to it on parade. In ordinary marching, the soldier is not required to keep exact time and cadence.

All changes of the order of battle of a battalion on the spot, consist in forming front to the rear, or to either side. The changes on a march are to place the troops in column, and to march forward, backwards, to either side, in an oblique direction; and in all these varieties of marching, to place them in order of battle towards any side at pleasure.

To form front to the rear, is most easily effected by facing to the right about. The third rank then becomes the first, and the whole position of the battalion is reversed. It is easy for the officers to change their places according to this alteration of position. If it is intended that the entire order of the battalion should remain unchanged, it would be necessary to bring round the front by a counter-march of the whole; a movement which, with a whole battalion, would require considerable time, even were it performed at the double quick step. (See Plate CCCLXXXI. Fig. 1.) If it be wished that the order of the rank only should be preserved, each platoon might be made to counter-march in itself; by which, however, the platoons would be thrown round, which has its inconveniences. (Fig. 2.) To make a whole battalion wheel about, is a movement much easier conceived than executed; besides, that it would then occupy a different position. (Fig. 3.) If performed round the centre, then one half of the battalion would be obliged to wheel backwards; while, on the other hand, it would be better that one half, before the wheeling, should face to the right about. (Fig. 4.)

Many methods may be imagined of forming front towards the flank. 1. The battalion faces to the right or left, and either form entirely by marching up, (Fig. 5.) or by deploying. (Fig. 6.) 2. By a single quarter wheel. (Fig. 7.) 3. By each company making one-eighth wheel, with the exception of the flank company forming the centre, which makes an entire wheel; towards which the others then march straight up to the flank of their next platoon, and take their proper place in the new front. (Fig. 8.) This is the only method at present practised. In all these methods the troops might be made to wheel equally well round the centre. (Fig. 9.)

There are two methods of placing the troops in column. 1. By forming in column; and, 2. by wheeling with any parts of the battalion at pleasure. In forming in column, the whole battalion, with the exception of the head division or section, faces to the right or left. All march off at once, in order to place themselves, according to their order, behind each other, and all behind the head or leading division. (Fig. 10, 11.) The reverse of this is deploying, in which a battalion in column places itself again in order of battle by a contrary movement. A battalion may also be formed on the centre, and the deploying likewise be performed from the centre; the one half of the battalion facing to the right, and the other to the left. (Fig. 12.) In this movement, it will be observed, 1. That the intervals between the divisions are almost entirely done away; and, therefore, that the wheeling cannot take place separately, nor, in case of a bend in the road, without making a halt; first behind, and then again before, in order that the rear sections may have time to advance. Farther, a troop, standing thus in column, cannot, without a tedious movement, form front to the flank. Finally, it is impossible, according to this method, to form in column upon a very small front; and if this were to be done by several battalions, it would not only cause the last battalion to go a considerable way to no purpose, but would often be attended with difficulties. The forming into column by wheeling is performed by each section of a battalion making a wheel of one quarter by itself; so that they all stand behind each other at intervals, corresponding to their front. When, after wheeling, the battalion marches so that the first platoon forms the head, it is called to the right; but if the wheeling has been to the left, and the eighth platoon has the head, they are said to march off to the left. (Fig. 13, 14.) In this manner, the march may take place, not only to the flank, but to the front, or the rear. In marching to the flank, all the sections wheel to the right or left, and march off at once. In marching forwards, all the sections wheel, except the one which forms the head, which marches straight forward; and as soon as it has passed the second section, the latter wheels again towards the opposite side, in the true line of march, and follows the first; the others, in the same manner, follow the second, wheeling as above, upon the same spot. (Fig. 15.) In marching to the rear, the head section makes a half, the others a quarter wheel. All the sections then march straight forward; and when the second is exactly on the spot where the first has just made its half wheel, the latter wheels again into the new line of march; and the like is done by the others, as they arrive at the same spot. (Fig. 16.) In the same manner a perfect counter-march may be executed; the head section making immediately a three-quarter's wheel; and the others, as they arrive at the same spot, making a half wheel. (Fig. 17.)

From this method of forming in column, the following advantages are derived. 1. When the road becomes more narrow, so that it is necessary to break off, this, as well as the march forwards again, can take place without halting. (Fig. 18.) 2. The column can instantly form front to the flank, merely by wheeling inwards, which is of great advantage, when any thing is apprehended from the enemy in that quarter. 3. The march proceeds immediately without farther preparation; and the columns may be formed on as large or as small a front as we please. The only disadvantage attending this method is, that it requires a tedious movement to place the troops in order of battle to the front of the column, whether this is performed by filing, which besides can only take place on the ground with a long column in a large plain; or by marching up, especially if the head section arrives first on the ground where it is intended to remain. In order to unite all possible advantages, it is usual to make the troops commence the march while the columns are formed by wheeling. On approaching more to the enemy in front, divisions are formed at half distance, which at length advance altogether, in order to place themselves thereafter in order of battle, by deploying in double quick time. The most simple mode of marching towards every side, and in all directions, is the flank march, with facing to the right or left. When moving under arms, in the neighbourhood of the enemy, and at short distances, this method is extremely useful; and the troops ought to be particularly well exercised in it. But it is not adapted for marches in general, because the columns would require to be immensely extended, in order to enable the soldier to march in this manner without constraint. For this reason the method has been invented of facing to the right with five or six, which is a mode of forming columns by wheeling with quarter platoons, very convenient on narrow roads, and which leaves room enough for the soldier to march unconstrained. The oblique march can be performed on very small distances by stepping out to the right or left, and the oblique step. On larger distances, it is usual to keep the two small sides of the right angled triangle, although it might be possible to wheel by sections into the direction of the large side, and preserving the respective distance and situation of the sections among themselves, to march into the new front, and then to wheel inwards again. (Fig. 19.) In proper marches, the sections wheel into the line of march, and afterwards step into the road precisely behind the first.
